Figure 2 An overview of the regulation of morphological differentiation and secondary metabolism in *S. coelicolor*. This simplified scheme illustrates the complexity of regulatory networks, highlighting the role of some of the critical alternative sigma factors and other regulatory molecules involved in the control of reproductive growth (sporulation) and secondary metabolism (antibiotic production) – see Section ‘Regulation’ for details. It should be noted that the central role of the Bld cascade is conditional on glucose being the carbon-source in the growth medium, implying the existence of alternative regulatory pathways that function during growth in other conditions. The indicated regulatory dependencies are not necessarily direct and, in some cases, can also operate in reverse: for example, BldD represses *sigH*. In *S. griseus*, the γ -butyrolactone, A-factor, regulates both sporulation and secondary metabolism.

Regulation of Development

As a consequence of many years’ analysis of mutants affected in morphological differentiation, *S. coelicolor* has proved a useful model to study streptomycete development (reviewed by Flardh and Buttner, 2009). Sporulation of this species occurs only during surface culture. In contrast, *S. griseus* can be induced to sporulate in submerged culture, and this has extended our understanding of the control of development. For surface grown cultures, mutants blocked in the initiation of aerial hyphae formation, resulting in a smooth colony surface, have a bald (Bld) phenotype: many *bld* mutants are unable to make the hydrophobic extracellular proteins involved in morphogenesis (see Section ‘Morphological Differentiation’), including chaplins and SapB. This phenotype is conditional on the medium and, in particular, the carbon source, used to support growth. For example, on a glucose-containing rich medium, *bld* mutants cannot produce SapB or develop aerial hyphae. When purified SapB is applied exogenously to these mutants (with the exception of the *bldF* mutant), hyphae can emerge from the substrate, although they do not differentiate into morphologically recognizable aerial hyphae. When pairs of *bld* mutants are grown close to each other, one may act as a donor of a diffusible activity that induces SapB production and hence the emergence of aerial hyphae. These extracellular complementation data have suggested a model in which each *bld* gene is directly or indirectly involved in the synthesis and response to a specific extracellular signaling molecule, defining a cascade where SapB is the final product (Figure 2). Many of these *bld* genes encode regulatory proteins. For example, *bldA* encodes a leucyl-tRNA (Section ‘Base Composition’). The *bldD* gene encodes a small DNA binding protein that represses the promoters of two developmental sigma factor genes, *bldN* and *whiG*, and one promoter of the stress-response sigma factor gene *sigH* (Section ‘Alternative Sigma Factors’). σ^{BldN} itself is responsible for transcription of the *chp* genes, encoding the hydrophobic proteins that contribute to the fibrous layer coating aerial hyphae (Section ‘Morphological Differentiation’). *bldK* is an exception in that it is not a regulatory gene: it encodes an oligopeptide transporter that imports a 655 Da peptide encoded, indirectly, by the *bldJ* locus. The *bld* cascade that commits the bacterium to aerial hyphal growth is believed to integrate factors like the energy balance and hyphal density with environmental conditions like nutrient availability and stress. Indeed, mutations in genes outside the cascade also result in a *bld* phenotype. For example, mutations in genes involved in primary metabolism such as *citA*, encoding citrate synthase, *cya*, encoding adenylate cyclase, and *acoA*, encoding aconitate citrase, result in a failure to form aerial hyphae because of an accumulation of organic acids. The group 3 sigma factor σ^{B} (Section ‘Alternative Sigma Factors’) and an atypical response regulator OsaB are both required for aerial hyphal growth on medium supplemented with ionic or non-ionic osmolytes.

The *bld* cascade activates expression of *ramR*, encoding the response regulator that in turn controls expression of the *ramCSAB* operon, specifying synthesis and export of SapB (Figure 2; see Section ‘Morphological Differentiation’). Mutation of *ramR* itself delays aerial growth, while its overexpression restores SapB synthesis and aerial growth in *bld* mutants and the *citA* mutant. For the latter, metabolic defects are not suppressed, indicating that RamR can uncouple morphological differentiation from metabolic signals. This is a consequence of RamR functioning as a critical regulator of the events leading to sporulation, and, in particular, because of its regulatory role in the commitment of emerging aerial hyphae to undergo sporulation. This pathway involves

transcriptional activation by RamR of the *ragABKR* operon encoding two subunits of an ABC transporter, a histidine kinase and a response regulator. A Δ *ragABKR* mutant develops defective branching aerial hyphae (branching is normally suppressed during aerial growth), reminiscent of those of a *whiG* mutant (σ^{WhiG} is the first group 3 sigma factor involved in the sporulation pathway; Section 'Alternative Sigma Factors'). Several regulatory pathways may modulate activation of σ^{WhiG} , representing an early checkpoint for commitment to sporulation. The RagK histidine kinase may sense the radically different environment encountered by the hyphae as they emerge into the air, activating the response regulator RagR that may, in turn, influence activation of σ^{WhiG} . In addition, the *rag* operon may be necessary for export of an as yet unidentified morphogenetic compound that influences differentiation of aerial hyphae. Examples of compounds that influence aerial development identified in other *Streptomyces* spp. are the γ -butyrolactone A-factor in *S. griseus* (see Section 'Regulation of Secondary Metabolism') and the antibiotic pamamycin in *S. alboniger*.

Mutants affected in subsequent differentiation of aerial hyphae do not generate normal mature spores and stay white instead of developing the normal gray color conferred by a spore-wall-associated polyketide pigment. These *whi* mutants have been grouped as 'early' or 'late' (Figure 2), early mutants failing to achieve full sporulation septation. σ^{WhiG} , encoded by the early *whiG* gene, transcribes two further early sporulation genes: *whiH* and *whiI*. The WhiH transcription factor belongs to the GntR family that, in addition to a DNA binding domain, possess a signal-sensing domain that typically responds to an acidic carbon metabolite. Despite its overall homology with response regulators, the WhiI protein lacks two key conserved residues in its putative phosphorylation pocket. A plausible model posits that these two transcription factors normally repress transcription of their own genes, but respond to signals at the cessation of aerial growth to become activators of late sporulation promoters.

In addition to the σ^{WhiG} -dependent early *whi* genes, the expression of two other early σ^{WhiG} -independent *whi* genes, *whiA* and *whiB*, is upregulated during aerial growth. Both the WhiB protein and the late sporulation protein WhiD belong to a protein family unique (and abundant – *S. coelicolor* encodes 10 such proteins) to actinomycetes. They contain four conserved cysteine residues, suggesting that they may respond to intracellular redox changes by disulphide bond formation or by chelation of a redox-active metal atom. By sensing redox changes at the end of aerial growth, they could coordinate orderly growth cessation: a characteristic of *whiA* or *whiB* mutants is formation of unusually long aerial hyphae. After growth cessation, all the early *whi* genes are needed for proper sporulation septation and transcription of late sporulation genes and operons. This includes regulation of *sigF* (Section 'Alternative Sigma Factors') and the *ftsZ2p* promoter that is activated to provide an increased amount of the FtsZ protein required for sporulation septation (Section 'Hyphal Growth and Cell Division').

Regulation of Secondary Metabolism

Many secondary metabolite biosynthetic gene clusters contain at least one cluster-specific regulatory (CSR) gene, often encoding a *Streptomyces* Antibiotic Regulatory Protein (SARP) or a transcriptional regulator of the LAL family (Large ATP-binding regulators of the LuxR family). The former are transcriptional activators containing a winged helix-turn-helix motif towards their N-termini that is also found in the OmpR family of proteins. The SARP family of proteins have been found only in actinomycetes, and mostly within the streptomycetes. A very complex set of regulatory cascades link physiological, environmental and developmental signals to expression of pleiotropic regulatory genes and ultimately these pathway-specific regulators, thereby controlling secondary metabolism after the main growth phase of the bacterium (Figure 2; reviewed by Liu et al, 2013; van Wezel & McDowall, 2011). Examples of the pleiotropic regulators are the products of the *bld* genes that also regulate the growth of aerial hyphae (Section 'Regulation of Development'). As discussed previously (Section 'Primary Metabolism'), high concentrations of both ammonium and inorganic phosphate in the growth medium negatively impact antibiotic biosynthesis. In nitrogen-limiting conditions, antibiotic biosynthesis is triggered by the highly phosphorylated guanosine nucleotide (p)ppGpp. Consequently, in these conditions, antibiotic production depends on the ribosome-associated ppGpp synthetase (RelA). This can be by-passed by mutations in the β -subunit of RNA polymerase of the kind that confer resistance to rifampicin: it is possible that these mutations mimic the effect of ppGpp binding to RNA polymerase and hence influence its activity for transcription after the main growth phase. Mutations that affect translation during this part of the life-cycle also have a significant impact on antibiotic biosynthesis. A mutation conferring streptomycin resistance within *rpsL*, encoding the S12 ribosomal protein, results in increased expression of ribosome recycling factor and this, in turn, increases gene expression during stationary phase.

The streptomycetes typically produce extracellular signals that regulate antibiotic biosynthesis. These signals are γ -butyrolactones. They are effective in nanomolar concentrations, and the best characterized is A-factor produced by *S. griseus*. Unusually, A-factor is required for both secondary metabolism (streptomycin and griseofur biosynthesis) and morphological development. A-factor, specified by the *afsA* gene, binds to its cytoplasmic receptor protein ArpA, thereby preventing the latter from binding and repressing the *adpA* promoter. AdpA is required for activation of transcription of both *strR*, the pathway-specific regulatory gene for streptomycin production, and other members of the *adpA* regulon, some of which are required for morphological differentiation. γ -butyrolactones produced by other species specifically regulate secondary metabolism. Examples are the virginiae butanolides controlling virginiamycin biosynthesis in *S. virginiae* and SCB1 that regulates production (possibly indirectly) of the pigmented antibiotics of *S. coelicolor*. For these examples, the receptor protein is also required for normal production of the cognate γ -butyrolactone and is encoded by a gene adjacent to that specifying production of the signaling molecule. Moreover, both genes are adjacent to secondary metabolite gene clusters whose regulation is controlled by the γ -butyrolactone. For example, in *S. coelicolor*, *scbA*, specifying SCB1 synthesis, and *scbR*, encoding the receptor protein, both lie next to a cluster of genes, the *cpk* genes, that specify synthesis of a 'cryptic' Type I polyketide. In the absence of SCB1, ScbR binds to the promoter of the pathway-specific

regulatory gene *cpkO* and represses its transcription. A second ScbR-like repressor, ScbR2, also controls *cpkO* expression. The *scbR2* gene is close to *cpkO* and the repressor protein, unlike ScbR, does not bind gamma-butyrolactones. The products of the *cpk* cluster were revealed when *scbR2* was deleted, as this effectively upregulates expression of both the CSR *cpkO* and, consequently, the CPK biosynthetic genes. This example of manipulating expression of a CSR of a given cryptic gene cluster to activate biosynthesis has also been achieved for another cryptic Type I polyketide synthase gene cluster in *S. ambofaciens* and could be applied to other examples of 'cryptic' biosynthetic pathways as part of drug-discovery programmes to extend the range of bioactive compounds produce by streptomycetes.

A pleiotropic regulator of antibiotic production in *S. coelicolor*, AfsR, shares in its N-terminal region significant amino acid homology with the SARP family of proteins, while containing ATP-binding sequences in its central region. AfsR plays a role in a signal transduction phosphorelay that regulates synthesis of the pigmented antibiotics Act and Red, and also the calcium-dependent antibiotic (CDA) specified by the *cda* cluster. A membrane-associated serine/threonine protein kinase, AfsK, when activated by an as yet unknown environmental cue, autophosphorylates and in turn phosphorylates cytoplasmic AfsR (and also DivIVA, Section 'Hyphal Growth and Cell Division'). AfsR-P then activates transcription of *afsS*, encoding a 63-amino acid protein that functions in an unknown way to enhance production of Act, Red and CDA. Other kinases (PkaG and AfsL) can phosphorylate AfsR, suggesting that it can integrate a variety of environmental signals.

A paradigm for understanding the complexity of regulation of synthesis of a given secondary metabolite concerns Act biosynthesis in *S. coelicolor*. In this example the CSR is the ActII-ORF4 regulator that controls Act biosynthesis. This CSR acts as a critical node in the regulatory network controlling Act biosynthesis, integrating information on nutritional status, growth and development among other factors. This is achieved largely at the transcriptional level as the *actII*-ORF4 promoter is extraordinarily complex (for a bacterial promoter region), in that it is itself a target for at least 10 regulatory proteins. These include AdpA, itself repressed both by a γ -butyrolactone-binding transcription factor (see above) and by BldD (linking morphological development with regulation of secondary metabolism). AdpA binds to the *actII*-ORF4 promoter and helps to recruit RNA polymerase thereby activating transcription and Act biosynthesis. Another AdpA-activated target gene is *bldA* (Section 'Base Composition'), so establishing a developmental positive-feedback loop, and this impinges on Act biosynthesis as the *actII*-ORF4 mRNA also contains a rare *bldA*-dependent UUA codon. A repressor of *actII*-ORF4 is DasR that regulates the global response to N-acetylglucosamine released on programmed cell death and autolysis of parts of the vegetative hyphae at the end of growth. This product is released from degrading cell walls and, once assimilated, is deacylated and phosphorylated. The resulting metabolite binds to DasR, relieving its repression of *actII*-ORF4.

The cyclic AMP receptor protein, Crp, involved in glucose repression in other bacteria, is an activator of *actII*-ORF4 expression as well as the CSRs for CDA and Red. Other regulators acting directly on *actII*-ORF4 and involved in nutritional responses are the xylose operon repressor; AfsQ1, an activator that responds to nitrogen excess; GlnR (Section 'Primary Metabolism'); DraR, part of a two-component system that responds to nitrogen excess; PhoP (Section 'Primary Metabolism'); and AtrA, itself regulated by PhoP. In addition, the *actII*-ORF4 promoter is a target for the two-component response regulators AbrC3 and AbsA2.

Regulation of secondary metabolism in streptomycetes includes other diverse mechanisms; this complexity is to be expected as the different bioactive products have a wide range of adaptive functions, many of which we do not yet understand. Consequently, several parallel and overlapping regulatory pathways can exist within a single species, coordinating production of one or more secondary metabolites in response to different environmental cues, and often linking production with developmental signals that trigger morphological differentiation.

Conclusion

Although more complex than most prokaryotes, and consequently often less amenable to research, *Streptomyces* spp. are continuing to offer exciting new paradigms as model systems in microbiology. As the genomes of more members of the genus are sequenced, and this information is assessed using functional genomic tools, a lot more information about this important family of bacteria will be added to that summarized in this article. This will contribute to increasing our knowledge of fundamental aspects of biology as well as offer insights into related, less experimentally tractable bacteria such as *M. tuberculosis*, and potentially provide vital new drugs to extend the 'antibiotic era' of medicine that is currently being seriously challenged by the evolution of multi-drug resistant pathogens.

Glossary

Adapter and anti-adapter proteins Proteins that regulate protein degradation by the ClpXP protease.

Ancillary factors Proteins or other molecules that influence RNA polymerase activity.

Antiporter A protein in cytoplasmic membrane that brings about exchange of external protons and a cellular ion/compound.

Electrophiles Compounds that accept electrons.

Eutrophic environments Environments made nutrient-rich primarily through human activity.

Inclusion bodies Precipitated and denatured proteins inside a cell. These are usually formed in bacteria when a heterologous protein is overproduced.

Periplasm Space between outer and cytoplasmic membranes in Gram-negative bacteria.

Pex proteins The core set of proteins induced in response to diverse stresses.

Porins Proteins in the bacterial outer membrane that form water-filled pores, permitting transport.

Proteome Complete protein profile of a cell.

Redox cycle A reduction reaction that generates unstable radicals. These give their electrons to oxygen generating reactive oxygen species (ROS). The radical is changed back to the original compound and becomes available for further ROS generation.

Sigma factors Small proteins that combine with the RNA polymerase core enzyme. The resulting RNA polymerase holoenzyme can transcribe various genes. Each species of RNA polymerase generally recognizes specific promoter sequences.

Transcriptome Complete gene transcription profile of a cell.

Abbreviation

cAMP	Cyclic AMP
GSR	General stress response
HARVs	High aspect to ratio vessels
HGH	Human growth hormone
HPK	Histidine protein kinase, the sensor kinase of the two component systems
IHF	Integration host factor
LpDH	Lipoyldehydrogenase
OMPs	Outer-membrane proteins
QH ₂	Hydroquinone
RNAP	RNA polymerase
ROS	Reactive oxygen species
RR	Response regulator
RR	Response regulator protein, also, a part of the two component systems.
rRNA	Ribosomal RNA
sRNAs	Small RNA
TIR	Translational initiation region
UTR	Untranslated region

Defining Statement

Bacteria counter stress at two levels, specific and general, to escape a given stress and to acquire greater robustness. I will discuss here the mechanisms of escape, increased cellular robustness, and the molecular mechanisms that enable a bacterium to shift from rapid growth mode to stasis and enhanced resistance.

[☆]*Change History:* August 2014. AC Matin added abbreviations, references, and further reading. The author made changes in sections 'General Stress Response' and 'Regulation of Stress Response.'

This article is an update of A. Matin, Stress, Bacterial: General and Specific, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 485–500.

Introduction

Bacteria, like other living things, require certain physicochemical conditions in order to thrive. Usable nutrients need to be sufficiently available, temperature and pH maintained within specific limits, and toxic influences absent. Under such optimal conditions, bacteria grow at maximal rates of which they are genetically capable. The animal gut flora encounters such conditions after the host has taken a meal, intracellular pathogens often immediately after invasion, and environmental bacteria in, for example, eutrophic environments. But such conditions are rare and fleeting, and as a rule, bacteria in nature exist under conditions that are not only suboptimal but can be outright hostile to their survival, exposing them to diverse kinds of stresses.

A common stress is lack of food. Thus, the gut flora by its rapid growth soon exhausts the nutrients passed on to the host intestine and progresses from feast to famine, and the same is likely true of an intracellular pathogen. While eutrophic environments are on the rise due to human activities, much of the natural environment nevertheless remains severely nutrient-poor. Oceans are estimated to have 0.8 mg carbon nutrients per liter, and the concentration of individual carbon compounds in fresh water is often as low as $6\text{--}10\ \mu\text{g l}^{-1}$. Similarly, soils as a rule possess little usable nutrients, as most of the 0.8–2.0% carbon in this environment is humus, which bacteria for the most part cannot use. In other natural environments, bacterial growth is restricted by the scarcity of other nutrients, such as nitrogen, phosphorus, and/or iron (Ghiorse and Wilson, 1988; Kaiser et al., 2014; Matin et al., 1989; Rohmer et al., 2011).

The fluctuating conditions in nature expose bacteria to additional stresses. Diurnal and seasonal changes in temperature can be significant, and a host of abiological and biological factors can result in exposure to a variety of insults, such as pH, osmotic, shear, and oxidative stresses. The pathogenic bacteria have not only to be adept at surviving these stresses during their extra-host existence but also to be able to cope with deleterious influences as they attempt to survive in the host in disease initiation. For example, to infect a host, *Salmonella enterica* serovar Typhimurium, which causes a typhoid-like disease in mice, has to survive passage through the stomach where the average pH over a 24-h period is as low as 1.5. It then invades the interior of the host by infecting the microvilli of the gastrointestinal tract, which are low-shear environments (Guo et al., 2000), and it is then ingested by the host macrophage, where additional insults await – oxidative stress, nutrient deprivation, and low pH. To meet such threats to survival, bacteria have evolved elaborate adaptive responses; these are the subject of this article with special emphasis on starvation, although other stresses are also considered.

The Stress Response is Two-Pronged

Bacteria meet the challenge to survival posed by stresses using a two-pronged strategy. One is aimed at neutralizing and escaping the specific stress that is encountered. This response tends to be unique to each stress; thus the proteins a bacterium needs to escape, for instance, oxidative stress are different from those it utilizes to escape starvation. This is termed the specific stress response. The second component of the stress response is aimed at preventing and repairing the damage that the stress might cause and is activated as an insurance policy, since there is no guarantee that the first response will succeed in preventing the deleterious effects of the stress. All stresses, if not neutralized, lead to a common outcome, namely damage to the cell biomolecules, and the second tier of the stress response is aimed at preventing and repairing this damage. Thus, this facet of the stress response results in making bacteria resistant not only to the stress that is experienced but also to others, and is thus termed the general stress response (GSR).

Specific Stress Response

Starvation

The first definitive indication that bacteria respond to stresses by a two-pronged strategy came when the proteomes of bacteria subjected to different stresses were examined. For example, starvation for carbon, nitrogen, or phosphorus resulted in the induction not only of proteins unique to that starvation condition but also to that of a core set of proteins that was common to all the starvation conditions (referred to as Pex proteins) (Groat et al., 1986). Exposure to stresses mechanistically different from starvation, *viz.*, oxidative, osmotic, pH, and others, also led to the induction of unique and common proteins, many of the latter being the same as the core starvation (Pex) proteins (Jenkins et al., 1988a). Based on these findings, it was proposed that the proteins unique to a specific stress were concerned in enabling the bacteria to neutralize that particular stress, while the core set of proteins was concerned with conferring resistance to stresses in general (Matin, 1991a; Matin et al., 1989). This has been found to be the case (Peterson et al., 2005a). In this section, I will discuss the physiological role of selected proteins that are concerned with the escape response; the function of the Pex proteins that confer general resistance is discussed in subsequent sections.

Examples of proteins concerned with escaping stresses are provided in Table 1. Starvation-escape response consists in the synthesis by bacteria of enzymes that amplify their capacity to obtain the scarce nutrient (Harder et al., 1977). This is accomplished either by increasing the concentration of the relevant enzymes or by synthesizing a new set that possess a higher affinity for the nutrient. Either way, a superior capacity is acquired to scavenge the scarce nutrient. The proteins that are induced can concern every metabolic feature: transport through the outer and cytoplasmic membranes, enzymes involved in substrate capture, and those responsible for subsequent flux through the metabolic pathways. Thus, when phosphate concentration falls below some $1\ \text{mmol l}^{-1}$ in the environment, cells increase the protein PhoE, which is a porin facilitating the passage of phosphate compounds

Table 1 Selected escape-response proteins

Protein	Function
<i>Phosphorous starvation</i>	
Pst	High-affinity phosphate transport system
PstS (also called PhoS)	Periplasmic Pi-binding protein required for PstS function
PhoE	Porin that facilitates Pi transport through the outer membrane
PsiB and PsiC	Glycerol phosphate transport systems
Bacterial alkaline phosphatase	Carbon-phosphorus bond lyase
<i>Carbon starvation</i>	
Periplasmic-binding proteins (e.g., MalE)	Enhanced transport (e.g., maltose)
Glucokinase	Substrate capture (glucose)
Lactate dehydrogenase	Substrate capture (lactate)
β – Galactosidase	Substrate capture (lactose)/metabolic potential amplification
CstA	Substrate capture (peptides)/metabolic potential amplification
Glycerol kinase	Substrate capture (glycerol)
Glucose-6-phosphate dehydrogenase	Enhanced flux through catabolic pathways
Phosphofructokinase	Enhanced flux through catabolic pathways
Pyruvate kinase	Enhanced flux through catabolic pathways
Aconitase	Enhanced flux through catabolic pathways
Isocitrate dehydrogenase	Enhanced flux through catabolic pathways
Malate dehydrogenase	Enhanced flux through catabolic pathways
<i>Other stresses^a</i>	
Aerobactin (iron starvation)	Iron chelator
Glutamine synthetase (nitrogen starvation)	Substrate capture
Kdp (potassium starvation)	High affinity K ⁺ transport
Superoxide dismutase (oxidative stress)	Decomposes superoxide
KatE (oxidative stress)	Catalase
KatG (oxidative stress)	Catalase
Thiol peroxidase (oxidative stress)	Thiol-dependent hydroperoxidase
Sulfate adenylyltransferase (oxidative stress)	Cysteine biosynthesis
Cysteine synthase (oxidative stress)	Cysteine biosynthesis
ChrR (oxidative stress)	H ₂ O ₂ quencher
Lysine decarboxylase (acid stress)	Generates cadaverine that buffers the cytoplasm
CadB (acid stress)	Brings about exchanges of cellular cadaverine for medium lysine
UreI (acid stress)	Increases membrane permeability to urea which, through urease activity, buffers the cytoplasm

^a Text in parentheses indicates the stress.

through the outer membrane into the periplasmic space of *Escherichia coli*. Here, it interacts with a high affinity-binding protein (PstS), also induced under these conditions, promoting efficient functioning of PhoE. The compounds thus transported to the periplasm are hydrolyzed by another protein induced by phosphate starvation, the bacterial alkaline phosphatase, generating Pi. Rapid transport of the latter across the cytoplasmic membrane is ensured by the fact that a high affinity Pi transport system, Pst (energized by ATP; K_m for Pi, 0.16 $\mu\text{mol l}^{-1}$), is concomitantly induced under these conditions, replacing the low affinity Pit system (energized by proton motive force; K_m for Pi, 25 $\mu\text{mol l}^{-1}$) that operates under phosphate-sufficient conditions (Harris et al., 2001; Matin et al., 1989).

This pattern has been demonstrated in several bacteria also when limitation for other nutrients is encountered. Carbon-scarce cells often also synthesize high affinity-binding proteins, for example, MalE, which binds maltose facilitating its transport into the cell. When *Pseudomonas* or enteric bacteria utilizing lactate or glucose as carbon source were subjected to the limitation of these substrates, they greatly increased the synthesis of lactate dehydrogenase or glucokinase, respectively. Concomitantly, there was a marked induction of several enzymes of glycolysis and tricarboxylic acid cycle, ensuring effective channeling of low levels of catabolites through them (Matin et al., 1976). Large amounts of glutamine synthetase, which catalyzes the first step in ammonium assimilation, are synthesized during ammonium limitation (Reitzer and Magasanik, 1986), and induction of high affinity substrate-capturing proteins occurs also during potassium and glycerol scarcity. In the former case, the cells shift to the Kdp system (high affinity; energized by ATP) from the Trk transport system (low affinity; energized by proton motive force) that is used when potassium is plentiful (Rhoads et al., 1976). Cells grown on nonlimiting concentrations of glycerol utilize a low affinity pathway for its catabolism whose initial step is catalyzed by glycerol dehydrogenase; under glycerol scarcity on the contrary, a high affinity pathway initiating with glycerol kinase is utilized (Martinez-Gomez et al., 2012). Iron-challenged cells increase the synthesis of the iron siderophore, aerobactin (Hantke, 1981). Thus, a combination of the synthesis of high affinity transport and other proteins coupled with a general increase in the level of metabolic enzymes ensures that the cells can effectively scavenge and utilize the scarce nutrient from the environment.

These measures can of course not always succeed in alleviating starvation. For instance, cells growing on glucose can synthesize any amount of enzymes to facilitate its utilization, but this would not help if this substrate becomes completely absent from the environment. An additional measure is therefore employed, which is to de-repress the synthesis of enzymes for substrates other than glucose counting on the chance that the constantly fluctuating conditions might promote their appearance in the environment. Thus, cells subjected, for instance, to glucose starvation also synthesize enzymes such as β -galactosidase and CstA, which confer on them the capacity to utilize lactose and peptides, respectively, thereby acquiring the capacity to cast a wider net for alleviating carbon starvation (Schultz and Matin, 1991).

Oxidative Stress

Ground state oxygen has two unpaired spins, and the constraints of quantum mechanics, and the resulting spin restriction, hinder its divalent reduction. This favors the univalent pathway that generates highly reactive (and toxic) oxygen species (ROS). Consequently, oxidative stress from ROS is a constant threat to bacteria and other living entities. Bacterial respiratory chains (like those of mitochondria) leak ROS (Imlay, 2008). Phagocytes possess a membrane-bound NADPH reductase, whose function is to catalyze one-electron reduction of O_2 to generate ROS so as to kill the invading bacteria (Babior, 1984). When plant cells come in contact with soil-dwelling bacteria, such as *Pseudomonas putida*, they release an immediate burst of H_2O_2 . Many electrophiles generated internally by bacteria or those found in the environment are also a source of oxidative stress. Examples are quinones, nitro-compounds, chromate, and several dyes; quinones such as plumbagin and juglone are secreted by plants as defense mechanisms against bacteria (Lin et al., 2010). These compounds are vicariously attacked by cellular metabolic enzymes such as glutathione and cytochrome *c* reductases, and lipoyl dehydrogenase (LpDH), which reduce them by one-electron transfer. The result is the generation of reactive radicals, such as semiquinones and Cr(V), which set up a redox cycle. In this process, the radical (e.g., semiquinone) transfers its electron to O_2 or, depending on the conditions to another molecule (e.g., NO_3), regenerating quinone and producing ROS or other equally destructive oxidizing agents (e.g., nitrosative radicals). With the continued activity of one-electron reducers, the quinone (or other such electrophiles) shuttles back and forth between its quinone and semiquinone valence states, producing large quantities of ROS. These compounds are referred to from here on as 'univalent reduction-prone' electrophiles.

That bacteria do indeed experience severe oxidative stress when exposed to univalent reduction-prone compounds was demonstrated by the use of the intracellular oxidative stress sensor 2', 7'-dihydrodichlorofluorescein (H_2DCFDA), which is taken up by the cells and emits green fluorescence in the presence of ROS. For instance, *E. coli* cells exposed to chromate do indeed emit green fluorescence (Figure 1). Proteome analysis showed that these cells induced several proteins concerned with combating oxidative stress, for example, superoxide dismutase, which decomposes the superoxide radical, and those concerned with cysteine and thiol biosynthesis, which are ROS quenchers. Mutants unable to synthesize these proteins proved more sensitive to chromate killing, and strains with bolstered capacity to synthesize antioxidant defense proteins, such as ChrR (Table 1; see below) less so compared to the wild type (Ackerley et al., 2006). Other examples of proteins that permit escape from oxidative stress are given in Table 1.

ChrR, mentioned above, belongs to a recently discovered class of enzymes that combat oxidative stress in a variety of ways. These enzymes bring about a simultaneous two-electron reduction of univalent reduction-prone electrophiles. Thus, for example, they convert in one step quinone into fully reduced and stable hydroquinone (QH_2), bypassing semiquinone formation. The experimental approach to determine if an enzyme reduces the univalent reduction-prone electrophiles by one- or two-electron pathway utilizes pure proteins and a source of electrons, namely NADH or NADPH. It takes advantage of the fact that cytochrome *c* is reduced by semiquinones but not by hydroquinones, and since reduced cytochrome *c* absorbs light of 550 nm wavelength, its reduction can

Figure 1 *Escherichia coli* cells exposed to $250 \mu\text{mol l}^{-1}$ chromate and treated with intracellular ROS sensor 2', 7'-dihydrodichlorofluorescein. Cells were examined at $\times 1000$ magnification with an Olympus BX60 upright fluorescence microscope. Note that the cells form snakes and fluoresce green; both are indicative of oxidative stress. Reproduced from Ackerley DF, Barak Y, Lynch SV, et al. (2006) Effect of chromate stress on *Escherichia coli* K12. *Journal of Bacteriology* 188: 3371–3381.

easily be monitored in a spectrophotometer, serving as a facile probe for semiquinone formation. It was found that when quinone was reduced by a number of different cellular enzymes, such as LpDH, large amounts of reduced cytochrome *c* were generated, indicating that the quinone was reduced by one-electron transfer and generated semiquinone. However, when the reduction was catalyzed by the enzyme ChrR, no reduction of the cytochrome was seen (Figure 2(a)). Thus, the latter enzyme bypassed semiquinone formation resulting in direct conversion of the quinone to QH₂ (Gonzalez et al., 2005).

In an extension of this experimental approach, limiting concentrations of quinone were used, which ensured that the reaction ceased because all the available quinone in the reaction mix was exhausted. Figure 2(b) shows that in such a situation when ChrR is added to an in-progress LpDH-catalyzed quinone reduction, cytochrome reduction is swiftly halted, indicating that the LpDH is no longer generating semiquinone. Addition of further quinone to the reaction mix reinitiated cytochrome *c* reduction but at a very low rate and this too was soon halted. The experiment thus indicated that when ChrR is present, quinone is made largely unavailable to LpDH, so semiquinone formation ceases. Experiments using other single-electron reducing enzymes have given similar results. Thus, not only ChrR constitutes a safe pathway for the reduction of univalent reduction-prone electrophiles, such as quinones, it is also effective in preempting their reduction by the one-electron reducers, thereby affording a two-way protection to the cell exposed to such electrophiles (Gonzalez et al., 2005).

Figure 2 (a) Reduction of cytochrome *c* monitored spectrophotometrically at 550 nm during LpDH- or ChrR-catalyzed reduction of 50 $\mu\text{mol l}^{-1}$ of a quinone species, benzoquinone. The appearance of reduced cytochrome *c* during the LpDH-catalyzed reaction indicates one electron transfer and generation of semiquinone, whereas the lack of this species in the ChrR-catalyzed reaction signifies a divalent mode of quinone reduction that generates QH₂ bypassing semiquinone generation. (b) Addition of ChrR to an LpDH-catalyzed reduction of limiting benzoquinone, at the point marked by arrow 1, rapidly arrested the reduction of cytochrome *c* relative to LpDH alone (dashed line). The addition of fresh benzoquinone (arrows 2 and 3) reinitiated cytochrome *c* reduction, but with ChrR now present, only little semiquinone is generated as indicated by very limited cytochrome *c* reduction. This indicates that the presence of the two-electron reducer, ChrR, preempts quinone reduction by the one-electron reducer, LpDH. Reproduced from Gonzalez CF, Ackerley DF, Lynch SV, et al. (2005) ChrR, a soluble quinone reductase of *Pseudomonas putida* that defends against H₂O₂. *Journal of Biological Chemistry* 280: 22590–22595.

There is in fact another level at which ChrR protects the cell against oxidative stress and that is by virtue of the fact that QH₂, which it generates, is an effective quencher of ROS, such as H₂O₂. Strains of *P. putida* devoid of ChrR and those overproducing this enzyme were grown in the presence of 3 mmol l⁻¹ H₂O₂. The different cell cultures exhibited lag phases of varying duration, following which normal growth was seen (Figure 3). The ChrR overproducing strain was the first to recover, followed by the wild type, and finally the ChrR mutant. The recovery correlated with the ability of each strain to remove H₂O₂ from the medium, indicating that the cellular ChrR bolsters this capacity. Protein carbonylation, which is an indication of oxidative damage, was greatest in the strain devoid of ChrR and least in the one overproducing this enzyme (Gonzalez et al., 2005).

Acid Stress

Escape from acid stress involves a combination of physicochemical processes as well as the use of special enzymes to ensure that the cytoplasm is not acidified. The former mechanisms include making the cytoplasmic electric potential ($\Delta\psi$) positive, so as to oppose the entry of protons that, of course, are positively charged. It also includes changes in the composition of cytoplasmic membrane so as to render it less permeant to protons. In *Clostridium acetobutylicum*, for example, exposure to low pH results in a decrease in the ratio of unsaturated to saturated fatty acids and an increase in cyclopropane fatty acid content. An increase in phospholipids with amino acid head groups is another measure that appears to be aimed at decreasing proton permeability of the cytoplasmic membrane (Baumeister and Lembcke, 1992; Matin, 1999; Sunamoto et al., 1982).

The enzymes involved are amino acid decarboxylases. A well-studied system involves lysine decarboxylation, which removes CO₂ from lysine and generates cadaverine. Cadaverine picks up a proton, thereby contributing to the de-acidification of the cytoplasm (Merrell and Camilli, 1999). The protonated cadaverine is exchanged for external lysine by the antiporter CadB. Another enzyme involved in the buffering of the cytoplasm is urease, which is thought to be critically important in the ability of the gastric ulcer/carcinoma-causing bacterium *Helicobacter pylori* to colonize the stomach. This bacterium synthesizes a special membrane protein called UreI that enhances urea transport into the cell. Urea is present in the gastric juice, but its permeation into the cell without UreI is too slow to be effective in enabling *H. pylori* to keep a neutral cytoplasm (Sachs et al., 2000).

General Stress Response

Cross-Protection

As mentioned above, cells respond to different insults not only by measures aimed at escaping a particular stress, but also by bolstering the cellular machinery meant to prevent and repair damage to biomolecules that may result if the escape response fails. The evolutionary basis for this is obvious: the external environment is often so unforgiving that the escape response strategies can often at best have only a partial success and survival necessitates that measures be activated to deal with the damaging effect of stresses. This is the function of the (Pex) core set of proteins that are synthesized regardless of the nature of stress, and they confer on the cell a robustness enabling it to withstand stresses in general.

Proteome analysis of cultures starved for glucose or other nutrients showed that the proteins synthesized fall into different temporal classes and that this synthesis program is essentially complete in 4 h after the onset of starvation (Schultz et al., 1988). The Pex proteins for the most part exhibit a sustained pattern of synthesis through this period, leveling off at its end. Consistent with their role in enhancing cellular robustness, it was found that inhibition of protein synthesis in a starving culture had a time-dependent effect on starvation survival, with maximum resistance developing after 4 h of protein synthesis during starvation (Reeve et al., 1984). That the core proteins are involved in conferring general resistance on the cell is further indicated by the fact that the cross-protection that starvation confers on cells against unrelated stresses, for example, heat, oxidation, hyperosmosis, and others

(Table 2), is also dependent on the time, up to 4 h, for which they have been starved. This phenomenon is illustrated in Figure 4(a) for the starvation-mediated cross-protection against heat, involving exposure to the normally lethal temperature of 57 °C. For the first 4 h after the onset of starvation, increasing resistance to heat is exhibited the longer the cells are starved, with maximal resistance being acquired within this period. The phenomenon is completely dependent on protein synthesis during starvation, since its inhibition by inclusion in the starvation regime of chloramphenicol or by other means prevents resistance development (Jenkins et al., 1988b).

Since the core protein set is synthesized regardless of the nature of stress, it follows that exposure to any stress and not just starvation should confer general resistance. This is indeed the case as is illustrated in Figure 4(b), which shows that cells exposed to adaptive doses of a variety of mechanistically unrelated stresses become more resistant to lethal concentrations of H₂O₂.

Role of σ^s in Resistance to Bactericidal Antibiotics

Recent studies have shown that the loss of σ^s renders stationary phase *E. coli* highly sensitive to the bactericidal antibiotics, gentamicin, ciprofloxacin, and ampicillin. The *rpoS* mutant experienced greater oxidative stress than the wild type as determined by the activation of the SOS response, and measurement of O●, and OH● by appropriate dyes. Further investigation showed that

mutational loss of antioxidant proteins, those that decompose ROS or supply NADPH for their activity namely the pentose pathway proteins (Grant, 2008; Ralser et al., 2007) – also results in the generation of greater oxidative stress in the mutants and heightened sensitivity to these drugs (Wang JH, Singh R, Benoit M, Keyhan M, Sylvester M, et al. (2014)). These findings promise to lead to measures for increasing the effectiveness of these antibiotics, an important result, given the serious threat posed by increased bacterial antibiotic resistance.

Biochemical Basis

The comprehensive resistance that stresses confer on cells is due to the fact that the core set of proteins are concerned with protecting vital cell biomolecules – proteins, DNA, cell envelope – from damage as well as to bring about repair of any damage that may still result. Envelope protection and reinforcement is afforded by proteins such as D-alanine carboxypeptidase, which likely increases peptidoglycan cross-linkage (Ghosh et al., 2008), and the products of the *otsBA* (*pexA*) genes which protect the cell membrane by promoting trehalose biosynthesis (Hengge-Aronis, 2002a). Furthermore, several periplasmic proteins concerned with the proper folding of proteins in this cell compartment are upregulated by stress; these include Dsb proteins that play a role in the formation or isomerization of disulfide bonds in proteins secreted into the periplasm, and peptidyl-prolyl isomerases concerned with the proper folding of proline-containing substrates. A consequence of stress is the accumulation in the periplasm of misfolded outer-membrane proteins (OMPs) due to the stress and excessive OMP synthesis. The OMP mRNAs are unusually stable. Two small noncoding RNAs, RybB and MicA, are induced under stress. These function as global mRNA repressors (Gogol et al., 2011a), and accelerate the decay of OMP mRNAs, thereby minimizing stress-induced damage by preventing excessive OMP production (Papenfort et al., 2006).

Protein repair

This is brought about by proteins called chaperones, which are a large and diverse group with indispensable physiological roles under all growth conditions, but which become more important under stress. Apart from conferring stress resistance, the chaperones are responsible for proper folding of nascent proteins and protein translocation across membranes. The chaperones DnaK, DnaJ, and GrpE, as well as GroEL and GroES are among the most extensively studied. These proteins are widely conserved through evolution: hsp70 is the eukaryotic homologue of the bacterial chaperone DnaK and hsp60 that of GroEL (Hendrick and Hartl, 1993).

It is thought that the nascent polypeptide chains or denatured proteins (referred to from here on as ‘substrate proteins’) bind DnaK and DnaJ (Figure 5). Interaction between the chaperones in the presence of ATP results in the formation of a ternary complex consisting of the substrate protein, DnaK–ADP, and DnaJ. Dissociation of this complex is mediated by interaction with GrpE and by binding of ATP. The final stages of folding/repair in most cases involve GroEL and GroES. This model is supported by several lines of evidence. For example, the denatured enzyme rhodanese aggregates in a buffer solution, but not in the presence of DnaK, DnaJ, and ATP, as the protein is protected by the ternary complex formation. Addition of GrpE, GroEL, and GroES results in efficient refolding and activation of the enzyme. In bacteria lacking these chaperones, newly synthesized proteins aggregate *in vivo*. However, this aggregation is prevented if the chaperone production is restored. Similarly, proteins imported into the yeast mitochondria from the cytosol show defective assembly in mutants missing hsp60 (GroEL homologue), and most soluble denatured proteins of *E. coli* form complexes with GroEL as a prelude to their repair. Strikingly, proteins in their native state do not interact with the chaperones. Exposure to stresses results in association of a large number of proteins *in vivo* with chaperones presumably to escape damage. In essence, chaperones are slow ATPases, which, when bound to ADP, have a high affinity for denatured proteins, but a low affinity for them when bound to ATP. These characteristics determine the duration of their action on an unfolded part of a protein and ensure the continuation of the process until renaturation is complete.

Bacteria are often used in industry and laboratory to overproduce heterologous proteins as the process is fast and economical. However, often the overproduced protein is denatured within the cell and precipitates, resulting in the formation of inclusion bodies. A protective role against this denaturation for DnaK was demonstrated by its overproduction in the cells. Human growth hormone (HGH) is produced industrially using *E. coli* transformed with a high copy number plasmid containing the *hgh* gene that encodes this hormone. In control cells producing normal levels of DnaK, the HGH produced in the cell formed massive inclusion bodies, but in cells overproducing this chaperone there was marked breakup of these bodies (Figure 6) and a corresponding increase in the soluble hormone (Blum et al., 1992). Recently, CysQ, another stress response protein has been shown to play a similar role (Lee et al., 2014).

DNA repair

Several enzymes induced by stresses are concerned with DNA repair. Examples are endonuclease III and IV, Dps (PexB), and AidB, which reverse DNA methylation. A role for DnaK in DNA repair has also been reported. A major mechanism for DNA repair is the SOS response, which is activated by many different stresses, such as starvation, oxidative stress, irradiation, and treatment with antibiotics that damage DNA. This response promotes various kinds of DNA repair such as excision repair. This is aimed at excising pyrimidine dimers and other bulky lesions found in damaged DNA. The enzymes involved are UvrABC endonuclease, which is made up of proteins encoded by the *uvrA*, *uvrB*, and *uvrC* genes, helicase II (encoded by *uvrD* gene), DNA polymerase I, and DNA ligase. The UvrABC endonuclease makes incisions on each side of the lesion, generating a 12 to 13 base pair oligonucleotide. Different components of the enzyme act separately in this process. UvrA and UvrB interact to form a UvrA₂UvrB complex, which identifies the DNA lesion and locally unwinds it, producing a kink in the DNA of 130°. This is followed by

dissociation of the UvrA protein and formation of a stable UvrB–DNA complex, which is acted upon by UvrC to make the incision. The function of helicase II is to release the oligonucleotide and to free UvrC after the excision of the nucleotide. The gap generated by the incision is filled by DNA polymerase I, which carries out the repair synthesis, and DNA ligase, which fills the remaining nick (Hoeijmakers, 1991).

Regulation of Stress Response

Shift in the cellular gene expression and protein synthesis profile under stressful conditions involves several factors, *viz.*, changes in the concentration of sigma factors, ancillary regulatory molecules, and chemical alteration in certain proteins. Salient examples of each will be discussed.

Sigma Factors

Sigma (σ) factors are small proteins that associate with the RNA polymerase (RNAP) 'core' enzyme and determine what promoter the resulting 'holoenzyme' will recognize (Figure 7). The core RNAP (abbreviated as E) is made up of four polypeptides, $\alpha_2\beta\beta'$. Examples of sigma factors that play a role in stress response are σ^{70} , σ^s , σ^{32} , σ^E and σ^{54} ; their holoenzymes recognize specific DNA sequences present in a region called the promoter that is located, as a rule, 10 and 35 nucleotides upstream of the transcriptional start site. The σ^{70} holoenzyme $E\sigma^{70}$ is indispensable under all growth conditions and is referred to as the vegetative sigma factor. The consensus promoter sequences recognized by three of these holoenzymes are $E\sigma^{70}$: –10: TATAAT, –35: TTGACA; $E\sigma^{32}$: –10: CATNTA, –35: CTTGAA; and $E\sigma^{54}$: GG–N₁₀GC. ($E\sigma^s$ -recognized promoters are discussed below.) It should be noted that considerable variations from these sequences are tolerated by different species of RNAP, the enzyme species differ in their promiscuity in this respect, and a given promoter sequence can be recognized by different RNAP depending on specific conditions. For example, during starvation or osmotic stress, the transcription of the gene encoding an oxidative stress protection protein, Dps (also known as PexB), depends upon increased cellular levels of $E\sigma^s$ (Lomovskaya et al., 1994). However, under oxidative stress, $E\sigma^{70}$ with the help of the ancillary factor, called the integration host factor (IHF), allows transcription of *pexB* without $E\sigma^s$ (Kolter et al., 1993). Other genes are also transcribed by different RNAP species depending upon the presence of modifying conditions.

While all of these holoenzymes have a role in different stresses, their major role is concentrated on particular conditions. Thus, $E\sigma^{70}$ primarily transcribes the exponential phase genes and those concerned with the stress-escape response; $E\sigma^{32}$, the heat shock and starvation genes; $E\sigma^s$, the genes that are commonly expressed under stresses in general; and $E\sigma^{54}$, genes of diverse functions

Figure 7 Schematic representation of RNA polymerase holoenzyme showing the 2.4 and 4.2 regions, which recognize respectively the –10 and –35 promoter elements. Reproduced from Madigan MT and Martinko JM (2006) *Brock Biology of Microorganisms*, p. vi. Upper Saddle River, NJ: Prentice Hall.

including those involved in starvation, flagellar synthesis, and in cell growth on nonpreferred substrates, such as environmental pollutants.

The RNAP holoenzyme most important in inducing the GSR in bacteria is $E\sigma^s$, as it controls the expression of some 140 core stress genes that are induced by diverse stresses and are responsible for this response. σ^s bears close homology with σ^{70} in critical regions of the sigma protein referred to as regions 2.4 and 4.2, which recognize respectively the -10 and -35 promoter elements. Indeed, $E\sigma^{70}$ and $E\sigma^s$ recognize many of the same promoters *in vitro*. *In vivo* however, under stresses such as starvation, despite the fact that σ^{70} is more abundant in the cells than σ^s , $E\sigma^s$ specifically targets the stress genes. Subtle differences in the promoter sequences and the role of ancillary factors account for this specificity.

Specific features of σ^s -recognized promoters

$E\sigma^s$ -recognized promoters differ from those that $E\sigma^{70}$ recognizes in following respects. (1) They possess special features around their -10 region. Thus, a cytosine (C) at -13 position (i.e., 13 nucleotides upstream of the transcriptional start site) and a thymidine (T) at -14 facilitate $E\sigma^s$ binding to the promoter. Indeed, the -13 C may antagonize $E\sigma^{70}$ binding due to the differences in charged amino acids in the two sigma factors. In one instance, introduction of C at this position in a $E\sigma^{70}$ promoter improved its recognition by $E\sigma^s$. Adenine (A)/T-rich stretch is also involved, TAA at positions -6 to -4 being a common feature of $E\sigma^s$ -recognized promoters; this feature may allow easier promoter melting (i.e., unwinding of the DNA strands to permit transcription). (2) $E\sigma^s$ can tolerate much wider deviations from consensus promoter sequences than $E\sigma^{70}$ and can, for example, recognize promoters with degenerate -35 sequences, possibly because it does not need such a sequence *in vivo*, or is able to recognize other sequences in place of this sequence. (3) While the requirement of a 17 base pair space between the -10 and -35 region is a strong preference of $E\sigma^{70}$, $E\sigma^s$ is more relaxed in this requirement. Indeed, many $E\sigma^s$ -recognized promoters exhibit -35 like elements at other locations. (4) Certain AT-rich sequences present upstream of the -35 region favor $E\sigma^s$ binding to the promoter; the C-terminal domains of the RNAP α subunit play a role in this. (5) Both $E\sigma^{70}$ - and $E\sigma^s$ -recognized promoters tend to possess -10 -like elements downstream of the transcriptional start site. Since early transcript complexes retain the sigma factors, these sequences cause the transcription to pause. σ^s is released more rapidly than σ^{70} from these complexes; thus the pause is shorter when $E\sigma^s$ is the transcriber, and this may facilitate $E\sigma^s$ -mediated transcription of promoters that are recognized by both $E\sigma^{70}$ and $E\sigma^s$ (Hengge-Aronis, 2002b).

Other factors involved in favoring $E\sigma^s$ -mediated transcription

Several *trans*-acting proteins seem to favor $E\sigma^s$ -mediated transcription over that of $E\sigma^{70}$. Examples are H-NS, IHF, and Lrp. The mechanisms are not understood. In the case of H-NS, one possible mechanism is that the binding of this protein to a promoter interacting with $E\sigma^{70}$, but not $E\sigma^s$, renders the promoter unavailable for transcription. Changes in core RNAP, cytoplasmic ionic composition, as well as DNA supercoiling can also influence what RNAP species will transcribe a given gene.

A major factor responsible for a shift to different RNAP species under stress is competition for the RNAP core enzyme. The core RNAP concentration in bacterial cell is limiting and different sigma factors have to compete for it. σ^{70} possesses highest affinity for the core enzyme of all sigma factors and is present in excess; this accounts for the predominance of $E\sigma^{70}$ in unstressed cells. In stressed cells, even though σ^{70} retains its quantitative dominance, the balance shifts to RNAP species containing the alternate sigmas. Several factors account for this. $E\sigma^{70}$ dissociates so that core RNAP concentration goes up. The effectiveness of σ^{70} to bind to core RNAP is impaired due to the activity of the stationary phase-specific protein Rsd, and the small 6S RNA. σ^s has the lowest affinity of all sigma factors for RNAP and its increased synthesis under stress notwithstanding, it never attains more than one-third the level of σ^{70} . Nevertheless, it becomes the most active sigma factor in stressed cells because proteins like Crl, by binding to $E\sigma^s$, greatly enhance its activity. The small nucleotide, guanosine tetraphosphate (ppGpp), has a similar role; this is discussed further below. Certain cell metabolites such as glutamate and acetate may also have a role in stimulating $E\sigma^s$ efficiency (Foster, 2007; Paul et al., 2004). The mechanism by which σ^s concentration increases under stress has received a lot of attention and is discussed below.

Ancillary Regulatory Molecules

Cyclic AMP (cAMP)

As stated above, the core stress genes responsible for general resistance are transcribed mainly by $E\sigma^s$ and other species of RNAP bound to alternate sigma factors. However, $E\sigma^{70}$ does have a role in stress gene expression. The stress genes that this polymerase species transcribes tend to have weak promoters, that is, they deviate from the canonical promoter sequence that $E\sigma^{70}$ recognizes. Consequently, the transcription of these genes depends on the availability of ancillary transcriptional factors. This is the case with several starvation genes concerned with uptake of different compounds, and their efficient metabolism when they are present at low concentration. These genes are transcribed if cAMP is available. cAMP binds a protein called CRP, and the resulting complex binds to a specific sequence (AGTGAN₆TAACA) present upstream of the promoters of these genes, facilitating transcription by $E\sigma^{70}$. cAMP is present in cells at low concentration under nutrient-sufficient conditions but is increased dramatically during starvation, thereby promoting the transcription of these genes by $E\sigma^{70}$. The cAMP-dependent stress genes, however, play no role in enhanced general resistance, since starved cAMP-deficient strains exhibit the same degree of cross-protection against stresses in general as do cAMP-proficient strains. The role of these genes appears to be confined to the escape response by encoding proteins that enhance the cellular scavenging capacity by improving cellular uptake and metabolic functions.

Given the similarity between the $E\sigma^{70}$ and $E\sigma^s$ promoters, the following finding is of interest: changing the position of the CRP-binding site in certain genes can alter promoter preference from $E\sigma^s$ to $E\sigma^{70}$ and vice versa.

Guanosine tetraphosphate (ppGpp)

The small nucleotide ppGpp has been studied intensively in the context of the stringent response, which refers to the phenomenon whereby amino acid starvation results in rapid downregulation of ribosomal RNA (rRNA) biosynthesis and ribosomes. It is now known that the concentration of this nucleotide goes up also in response to starvation for other nutrients as well as in stresses. Its synthesis, initially as pppGpp (which is later dephosphorylated to ppGpp), involves two pathways in *E. coli*: by the ribosome-associated protein RelA, when the ribosome A-site contains an uncharged tRNA during amino acid starvation, and by the protein SpoT, which is responsible for ppGpp synthesis in most other stresses. SpoT can also degrade ppGpp and thus has a dual role. A strain of *E. coli* missing both RelA and SpoT (referred to as ppGpp^o strain) cannot synthesize this nucleotide and fails to lower its ribosome production under starvation conditions; such strains are referred to as relaxed strains. In other bacteria, for example, *Streptococcus mutans*, additional enzymes appear to be involved in ppGpp synthesis, such as RelP and RelQ.

In general, ppGpp positively affects the transcription of stress-related genes and negatively those related to growth. It exerts its regulation by binding to $\beta\beta'$ subunits of RNAP near its active site, as has recently been confirmed by crystal structure. This regulation is affected by several mechanisms, such as direct effect on the rate of formation and stability of the open complex, interference with promoter clearance (which obstructs further rounds of transcription), and competition with nucleotide triphosphates used in mRNA synthesis.

A major role of ppGpp in the stress response is that it increases the ability of σ^s (and that of other minor sigma factors) to compete with σ^{70} for binding to the core enzyme. This has been shown in *in vitro* transcriptional assays and is supported by the finding that ppGpp-deficient cells exhibit decreased fractions of both σ^s and σ^{54} bound to the core polymerase. The protein DksA may have a role in augmenting this effect. As can be expected from these findings, absence of ppGpp greatly compromises starvation survival, and proteome and transcriptome analyses have shown that this is because of the lack of stress protein synthesis; instead, the cells continue to express growth-specific proteins. Thus, ppGpp is a necessary adjunct to σ^s for stress survival, and although much of this effect is likely to be affected by ensuring σ^s function, some are likely to be directly due to ppGpp activity.

ppGpp has important roles also in growing cells, where it is required for amino acid synthesis – a deficient strain cannot grow in the absence of exogenously provided amino acids. Further, ppGpp deficiency affects bacterial virulence, for example, expression of genes of pathogenicity islands (Magnusson et al., 2005).

Chemical Alteration in Proteins

Protein phosphorylation

An important mechanism in bacteria for sensing starvation and other stresses, which involves chemical alteration of proteins, is the so-called two-component system. One component of this pair is a histidine protein kinase (HPK) that autophosphorylates at a conserved histidine residue. In response to specific stimuli, the phosphorylated form is stabilized; for this reason, it is also called the 'sensor kinase.' In turn, the HPK phosphorylates the response regulator (RR) protein at a conserved aspartic acid residue. This phosphorylated form of the protein then activates transcription of the target loci. Several pairs of such proteins have been found; these initiate special adaptive strategies in response to specific environmental cues. The HPKs of different systems share homology of about 100 amino acids at their C-terminus; the RRs share homology in the 130 amino acid segments of their N-terminal ends. Among the environmental stimuli sensed by the different two-component systems are phosphate and nitrogen starvations, osmotic changes, and chemotactic stimuli. Here, the phenomenon is illustrated in the context of sensing phosphate starvation.

As stated above (Table 1), several genes are induced in response to phosphate starvation; together these genes are referred to as the phosphate regulon. This regulon is under the control of the *phoBR* operon encoding the PhoB and PhoR proteins. The PhoB protein is a positive regulator of this regulon, since:

1. Mutations in *phoB*, which inactivate the protein, or deletion of this gene, render the phosphate regulon noninducible.
2. Sequence analysis shows that upstream of the *phoA*, *phoBR*, *phoE*, and *pstS* (*phoS*) promoters is a highly conserved 18-bp region (CTNTCATANANCTGTCAN) called the phosphate box. *In vitro* studies demonstrate that purified PhoB protein binds to the phosphate box and that this binding is required for the transcription of the phosphate regulon genes.
3. PhoB bears close homology to the RRs in other systems, such as NtrC (involved in sensing nitrogen starvation) and OmpR (involved in sensing osmotic stress).

The *phoR* gene has a hydrophathy profile typical of a membrane protein, and it shows homology to the HPK family of proteins. Like other sensor kinases, it autophosphorylates, a condition that is stabilized by phosphate starvation. It then phosphorylates PhoB, which activates the transcription of the phosphate regulon as discussed above.

Protein oxidation

This type of chemical alteration is involved in activating genes that protect against oxidative stress specifically in response to the ROS, H_2O_2 , and O_2^- . A more general mechanism that activates many of the same genes in response to diverse stresses is controlled by σ^s , as discussed above.

H_2O_2 is generally sensed by the transcriptional factor OxyR and O_2^- , by the SoxR/SoxS proteins, although the two systems probably overlap. H_2O_2 directly oxidizes OxyR. The conserved cysteines, at positions 199 and 208, are in free thiol form in OxyR; H_2O_2 converts them to disulfide form. The resulting conformational change, which has been documented by crystal structure, enables OxyR to activate the transcription of genes involved in escape from oxidative stress (Table 1). Upon removal of the H_2O_2 stress, OxyR is reduced by glutaredoxin 1.

The SoxR protein is constitutively synthesized and also becomes activated by direct oxidation, in this case by O_2^- . The protein is a homodimer with two $[2\text{Fe-2S}]$ centers per dimer; these centers are the loci of redox changes, that is $[2\text{Fe-2S}]^{1+} \rightleftharpoons [2\text{Fe-2S}]^{2+}$ conversion. The oxidized SoxR activates *soxS* gene transcription, which in turn induces a collection of genes called the *soxRS* regulon (Figure 8). These genes encode enzymes that can decompose O_2^- (Table 1) as well as repair the damage to DNA that may result from oxidative stress, such as the endonuclease IV, mentioned above. At the termination of the stress, SoxR is reduced by an NADPH-dependent SoxR reductase (Storz and Imlay, 1999).

Regulation of σ^S Synthesis

As stated above, σ^S is the most important regulatory element in the GSR. Its cellular levels and/or activity increase in response to starvation for diverse individual nutrients as well as other stresses, and how this is accomplished is now understood in some detail at all three levels of control – transcriptional, translational, and posttranslational. I will discuss the results mainly in the context of starvation stress, unless the available information is confined to another stress.

Transcriptional control

The *rpoS* gene is located in an operon downstream of the *nlpD* gene and is transcribed from two promoters, one within the *nlpD* gene and the other upstream of this gene. Use of transcriptional fusions suggested regulation in *E. coli* at this level under starvation, and by ppGpp. However, direct measurement of *rpoS* transcription in *E. coli*, by quantifying the *rpoS* mRNA levels and determination of its half-life, indicated that enhanced transcription has no role in the observed increased levels of this sigma factor under carbon starvation. More recently, the BarA-UvrY two-component system has been found to stimulate *rpoS* transcription (Mukhopadhyay et al., 2000). Also, proteins have been identified that negatively regulate the transcription of this gene; these include the Fis and the ArcA-P proteins; cyclic AMP too has a similar role (Hirsch and Elliott, 2005). K173 of the RpoS protein may also play a role in regulating *rpoS* transcription.

Translational control

The main *rpoS* transcript contains an unusually long untranslated region (UTR), which is central to its translational control. The UTR may form two types of hairpin structures. One of these sequesters the translational initiation region (TIR) by pairing with a complementary sequence present within the coding region of the *rpoS* mRNA (called the antisense element), thereby making it unavailable to the ribosomes for translation. Other hairpins may form due to complementary sequences within the UTR. It is possible that both types of secondary structures have a role in regulating *rpoS* mRNA translation, although the involvement of the antisense element-mediated secondary structure in this regulation has not been documented yet. But considerable evidence is available indicating that secondary structures within the UTR minimize *rpoS* translation in unstressed cells and that their relaxation under certain stresses is the major reason for increased cellular σ^S concentration (Figure 9). Small noncoding RNAs (sRNAs) and the RNA-binding protein, Hfq, play a role in this phenomenon. For example, the sRNA, RprA, possesses a complementary sequence to

Figure 8 Schematic of SoxRS regulation of the genes involved in defense against O_2^- radical. The change in the configuration of the SoxR protein upon oxidation by O_2^- is schematically represented to show that in its altered configuration, it can activate SoxS transcription, which in turn activates the individual genes of the SoxRS regulon. Reproduced from Matin A (2001) Stress response in bacteria. In: Bolton S (ed.) *Encyclopedia of Environmental Microbiology*, vol. 6, pp. 3034–3046. New York: John Wiley and Sons.

the UTR stretch of *rpoS* mRNA, which is involved in hairpin formation. Base pairing and hydrogen bonding by this sRNA is able to unfold the hairpin, free TIR, and permit translation to proceed. Another sRNA, DsRA, is induced under cold stress and promotes *rpoS* translation by a similar mechanism. ArcZ and GcvB sRNAs also perform similar roles; the latter is encoded by the intergenic region of the *pst* operon. The CsdA protein and the CspA family of RNA-binding proteins likely assist in the DsrA annealing with the UTR while also stabilizing the *rpoS* mRNA; the CspC and CspE proteins stimulate *rpoS* translation possibly by affecting the mRNA structure, and the histone-like protein, HU, likewise stimulates *rpoS* translation. In contrast, the OxyS sRNA, down-regulates *rpoS* translation, and so do a number of proteins, e.g., the LrhA protein, and RNase III, which degrades the *rpoS* mRNA (Battesti et al., 2011; Hussein and Lim, 2011).

Under phosphate starvation, the synthesis of σ^S is thought to be regulated at the translational level (Mandel and Silhavy, 2005), but its mechanism is not known. Some five other sRNAs are known to affect *rpoS* translation, but none of these appears to have a role under these starvation conditions. It is possible that an as yet undiscovered sRNA is involved or that the control is exerted through modulation of the antisense element-mediated hairpin. Additional possibilities involve regulation through a variety of proteins that are known to regulate *rpoS* translation. These include the nucleoid protein HU that binds two regions in the *rpoS* mRNA and may influence its secondary structure; the histone-like protein StpA; the cold shock proteins CspC and CspE; a PTS protein; and DnaK. It is known that PhoB-P stimulates translation of *rpoS* mRNA, and it is surmised that the former may activate the transcription of an as yet unknown sRNA that is responsible for facilitating *rpoS* mRNA translation. An additional reason for the increase in RpoS levels under phosphate starvation is stabilization of this protein as is discussed below.

Figure 9 The untranslated region (UTR) of the *rpoS* mRNA that encodes σ^S . Note that the sequences upstream of the translational initiation codon (ATG) of the RNA includes regions of internal complementarity that result in the formation of a hairpin structure. This prevents the availability of the initiation codon. The small noncoding RNA, RprA, has regions of homology to the UTR of the *rpoS* mRNA (shown in red; B). Hydrogen bonding between the homologous regions of RprA and *rpoS* mRNA opens the hairpin, permitting translation (C). Reproduced from Matin A and Lynch SV (2005) Investigating the threat of bacteria in space. *ASM News* 71(5): 235–240. Washington, DC: American Society for Microbiology.

Posttranslational control-increased RpoS stability

It was thought that the control of σ^s synthesis in carbon starvation in *E. coli* occurred at the translational level. Direct measurements of *rpoS* mRNA translational efficiency, however, disproved this notion and showed that the increase under these conditions is solely due to enhanced stability of the sigma protein (Figure 10). The experimental results shown in Table 3 indicate this fact. In this experiment, the rates of *rpoS* mRNA and σ^s synthesis and their half-lives were measured, which permitted calculation of the *rpoS* mRNA translational efficiency, that is, the σ^s protein synthesized per unit of its mRNA. *E. coli* cells were cultured in a glucose-limited chemostat in order to precisely establish the relationship between dwindling glucose concentration in the medium (with decreasing dilution rate) and the above mentioned parameters (Table 3). As the available glucose diminished, both σ^s synthesis rate and *rpoS* mRNA translational efficiency declined. Meanwhile, however, the stability of the sigma protein increased from 7- to 16-fold, accounting for the observed overall increase in the cellular levels of σ^s (Zgurskaya et al., 1997); this was subsequently conformed (Mandel and Silhavy, 2005).

What accounts for the instability of the σ^s protein under carbon-sufficient or other non-starvation/stress conditions? The answer to this question was provided by the discovery that a specific protease, called ClpXP, which is composed of two proteins, ClpX and ClpP, is involved in this regulation (Schweder et al., 1996). It rapidly degrades σ^s in unstressed cells, but not in those experiencing starvation (Figure 10). ClpP is a tetradecameric peptidase and has 14 active sites. ClpX is a hexameric ATPase, which binds to one or both ends of the ClpP chamber (Figure 11). ClpX binds directly or indirectly to proteins to be degraded and, using the energy provided by its ATPase activity, feeds them into the ClpP chamber. ClpX belongs to a family of proteins referred to as AAA+ATPase (ATPases associated with diverse cellular activities), and directly binds to proteins containing a short C-terminal sequence ('tagon'). The tagon is added by SsrA, or tmRNA to, for example, proteins with defects due to stalled ribosomes or other factors, causing these proteins to be rapidly degraded by the ClpXP protease. (It is estimated that some 5 proteins per thousand that *E. coli* synthesizes are destroyed by this quality control mechanism (Baker and Sauer, 2012; Moore and Sauer, 2007a).)

Figure 10 Comparison of σ^s stability in exponential phase (solid symbols) and stationary phase (open symbols) cultures in *clpP*-proficient (circles) and *clpP*-deficient (squares) backgrounds. Note that in a wild-type background, σ^s is stable only in the stationary phase, but in a mutant missing the Clp protein, it is stable in both the phases of growth. Reproduced from Schweder T, Kyu-ho L, Lomovskaya O, et al. (1996) Regulation of *Escherichia coli* starvation sigma factor (σ^s) by ClpXP protease. *Journal of Bacteriology* 178(2): 470–476.

Source: Reproduced from Zgurskaya HI, Keyhan M, and Matin A (1997). The σ^s level in starving *Escherichia coli* cells increases solely as a result of its increased stability, despite decreased synthesis. *Molecular Microbiology* 24(3): 643–651.

Figure 11 Schematic representation of native protein degradation by ClpXP protease. The ClpX component of the protease binds the substrate protein and unfolds it by its ATPase activity. The unfolded protein is translocated through the ClpP chamber, a process that also requires ATP, and is degraded; the resulting peptide fragments are released. Reproduced from Kenniston JA, Burton RE, Siddique SM, et al. (2004) Effect of local protein stability and the geometric position of the substrate degradation tag on the efficiency of ClpXP denaturation and degradation. *Journal of Structural Biology* 146: 130–140.

If ClpXP protease can degrade σ^s in exponential phase cells, why does this protein become resistant to this protease in the stationary phase? The answer to this and related questions has revealed involvement of a control mechanism involving adapter and anti-adapter proteins. While, as mentioned above, ClpXP can recognize proteins that are candidates for degradation, it does not recognize RpoS and requires the adapter protein RssB for gaining access to it. Schweder et al. (1996) showed that a stretch of amino acids spanning K173 to K188 residues in RpoS protein was required for its cleavage by the ClpXP protease. Subsequent work has shown that K173 is essential for RpoS cleavage: K173/E mutation abolishes RpoS proteolysis. Also, E174 and V177, although not absolutely required, facilitate this degradation (Becker et al., 1999). It is likely that RssB binding alters the conformation of RpoS, thereby exposing the site situated close to the N-terminus of this protein that binds to ClpX.

Under non-starvation conditions RssB maintains an active configuration promoting RpoS degradation, and its inactivation under starvation accounts for the increased stability of σ^s . RssB is a homologue of RR proteins, mentioned above, but is unique in its C-terminal output domain. By analogy to other RRs, its activation may require phosphorylation, and it may be dephosphorylated, for instance, in starving cells due to the ArcB/ArcA two component system. ArcB senses the redox status of quinones; when these are oxidized, disulfide bond formation within ArcB results in its inability to autophosphorylate (Malpica et al., 2004) resulting in dephosphorylation of ArcA, which is thought to donate the phosphate group to RssB. Thus, RssB would be primarily dephosphorylated and may be inactive for this reason in starving cells leading to increased RpoS stability. However, it is not certain that phosphorylation of RssB is essential for its activity, since removal of the aspartate residue from RssB, which is thought to be the phosphorylation site, does not inactivate it. Another explanation for RssB inactivation involving anti-adapter proteins has emerged. Three such proteins are known, IraP, IraM and IraD, which are induced in response to different stresses. Thus, IraP is induced under phosphate starvation, and IraD under conditions leading to DNA damage (Battesti and Gottesman, 2013). RssB has low cellular levels and the antiadapters are able to saturate it. Despite this shared activity, they do not bear structural homology, although several contain conserved RR domains, and their activity involves interaction with the flexible N-terminal domains of the ATPase components of the proteases. ppGpp, a global regulator of stringent response (see above), is a positive regulator of the *iraP* promoter; this may further explain the observed up-regulation of σ^s by ppGpp (Gentry et al., 1993). Additionally, H-NS, a histone-like protein, negatively regulates σ^s by modulating the translational efficiency of *rpoS* mRNA and the stability of newly synthesized σ^s . H-NS is a DNA-binding protein known to regulate genes at transcriptional level. The precise molecular mechanisms by which it controls σ^s at the post-transcriptional level remain to be fully elucidated (Barth et al., 1995; Yamashino et al., 1995). Its negative influence on σ^s stability is likely mediated by the suppression of *iraM* and *iraD* expression.

It is interesting to note that the K173-K188 region corresponding to 519–564 nucleotides of the *rpoS* mRNA constitutes the antisense element, which as mentioned above, may also have a role in translational regulation of Sigma S synthesis, and that, as already mentioned, K173 may be important also in transcriptional control. Thus, the K173-K188 stretch of the RpoS protein could be involved in regulating Sigma S synthesis at all three levels of regulation.

Activity control

Control at the level of activity of σ^s evidently operates in nitrogen starvation. Under these conditions, the core set of proteins are still synthesized even though σ^s levels show only a very modest increase. Thus, it is thought that the sigma protein is more active under these conditions. The factors that may account for this are hypothesized to be those that increase the competitiveness of σ^s for RNAP. These have been discussed above.

Regulation under low-shear/simulated microgravity conditions

Low-shear environments, such as brush border microvilli of the gastrointestinal, respiratory, and urogenital tracts (Guo et al., 2000), are common routes of microbial infection. Low shear environments closely resemble microgravity conditions experienced by astronauts during space flight. There has therefore been considerable interest in studying the biological effects of these conditions. On Earth, the effects of such environments are simulated by the use of a special cultivation equipment that utilizes high aspect to ratio vessels (HARVs). There is strong evidence that these conditions weaken the human immune response (Stowe et al., 2011) and make bacteria more virulent and stress-tolerant (Lynch et al., 2004; Wilson et al., 2002); these have obvious implications for the control of disease on Earth and on astronauts' health. Studies on the regulation of this phenomenon have resulted in some intriguing findings. Thus, the increased bacterial resistance that low-shear environments confer on bacteria appears to be independent of σ^S in exponential but not in stationary phase. Further, these environments markedly enhance *rpoS* translational efficiency regardless of the growth phase and promote σ^S instability, especially in the exponential phase. Since both these regulatory phenomena involve macromolecular folding pattern, the findings raise the possibility that low-shear/microgravity environments can influence these patterns.

Sensing starvation

Given that the regulation of the starvation response differs depending on the missing nutrient, it seems likely that the dearth of different nutrients is sensed by different mechanisms. The sensing mechanism in the case of carbon starvation could be an effector that inactivates RssB or ClpXP. Recent reports indicate that an increase in denatured proteins may have a role. Starvation affects fidelity of ribosomes, resulting in the synthesis of abnormal proteins with a proclivity for oxidation. The latter sequester Clp, impairing ClpXP activity, resulting in the stabilization of σ^S . In this view, starvation is sensed by the increase in aberrant proteins. Phosphate and nitrogen starvations may involve the PhoBR- and NtrBC-sensing systems mentioned above (Battesti et al., 2011). In *P. putida*, a G-protein, called FlhF, which is situated at the cell pole and controls flagellar localization on the cell, may be involved in sensing stress, as its absence robs the cell of the capacity to develop the general stress resistance (Pandza et al., 2000).

Concluding Remarks

It is evident that in response to hostile and frequently fluctuating conditions in nature, bacteria have evolved highly sophisticated mechanisms that permit them to swiftly shift between rapid growth and static survival modes. Our understanding of this phenomenon has enhanced greatly in the last two decades, and further progress is likely to yield information that will permit better control of bacterial growth – its enhancement toward beneficial ends, such as ecosystem management, industrial processes, and bioremediation, as well as its mitigation, as in disease.

Glossary

Homologues Genes sharing common ancestry, often determined by structural comparison.

HSE Heat shock element, it is a sequence in the promoter region of heat shock genes to which HSF binds.

HSF Heat shock transcription factor.

HSP Heat shock protein, chaperones, proteases, and regulatory proteins produced in response to temperature changes and other stresses.

MDR Multidrug resistant microorganism.

Operon Genes within the same transcriptional unit under the control of a common promoter element.

Regulon A set of genes under the control of a common regulator.

Repressor A protein or a regulatory element that inhibits transcription or translation, respectively.

Sigma factor It is the subunit of bacterial RNA polymerase needed for initiation, it is the major influence on selection of promoters.

Abbreviation

CIRCE controlling inverted repeat of chaperone expression

ECF extracytoplasmic function

ER endoplasmic reticulum

HAIR HspR-associated inverted repeat

HS heat shock

HSE heat shock element

HSF heat shock transcription factor

HSPs heat shock proteins

RNAP RNA polymerase

ROSE repression of heat-shock gene expression

SD Shine–Dalgarno

TBP TATA element-binding protein

TFB transcription factor B

Defining Statement

All living cells, from microorganisms to human cells, respond to a temperature upshift by transiently increasing the rate of synthesis of a set of proteins denominated heat shock proteins (HSPs), which maintain protein homeostasis by alleviating protein misfolding defects and aggregation, thus protecting the cells from damage. The increase in HSP levels is mainly due to the induction of transcription of the corresponding genes. Although the HSPs are among the most conserved proteins in nature, the mechanisms responsible for the transcriptional control of heat shock (HS) genes vary greatly. Bacteria, for instance, can control HS gene expression either negatively or positively, using either repressors that act by inhibiting HS gene expression at normal temperatures being inactivated at high temperatures, or alternative sigma factors that once activated induce transcription during heat shock, or in some bacteria both mechanisms take place. HS response has also been linked to antimicrobial resistance in pathogenic bacteria. In eukaryotic microorganisms like *Saccharomyces cerevisiae* induction of the HS response occurs by the activation of a heat shock transcription factor (HSF1) which exists constitutively as a trimer bound to a specific DNA element, the heat shock element (HSE), present in multiple copies in HS gene promoters. In higher eukaryotes a family of HSFs is observed, with mammalian cells containing four members: HSF1, HSF2, HSF3 and HSF4. Each of them possesses unique and overlapping functions, exhibiting

[☆]*Change History:* August 2014. SL Gomes and RCG Simão have updated the text and further reading.

This article is an update of S.L. Gomes, R. de Cássia Garcia Simão, Stress Responses: Heat, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 464–476.

tissue-specific patterns of expression, multiple post-translational modifications and interacting protein partners. These HSFs are present as monomers under physiological conditions, differently from *S. cerevisiae*, with HSF1 being the most potent and dominant. Activation of HSF1 occurs by the formation of trimers and extensive post-translational modifications, followed by its binding to the HSEs in the HS gene promoters. The control of HS gene expression in Archaea is not well understood, but a repressor has been characterized which is inactivated by a temperature upshift. HSPs have shown to be involved in addition to the HS response in the control of the cell cycle. The evidence being that accumulation of misfolded proteins in both bacteria and yeast, for instance, has been observed to cause G1 arrest. HSPs have also been strongly associated with microbial infections and with human diseases such as cancer and neurodegenerative diseases making the study of these proteins of even greater importance.

Introduction

The viability of all organisms crucially depends on the integrity of its constituent components, correctly folded proteins being one of the most important actors in all cellular processes. The folding state of proteins within cells is monitored by an energy-dependent quality control network of ATP-dependent proteases and molecular chaperones, which operates under all growth conditions but becomes extremely important during stress. In order to maintain homeostasis for protein folding, cells tightly regulate the expression of chaperones and proteases to compensate for environmental perturbations. Exposure of cells and organisms to high temperatures can cause misfolding and aggregation of proteins, which if not acted upon can lead to cell death.

The heat shock (HS) response is the way by which cells counteract to prevent the potential damages due to temperature upshift and consists in the induction of almost all the universally conserved HS genes. These genes encode chaperones, proteases, and other stress-related proteins, which play important roles in helping cells cope with the toxic effects due not only to high temperature exposure but also to several other environmental stresses, such as starvation for carbon or amino acids, DNA-damaging agents, oxidative stress, and heavy metals.

The first report of the HS response was by Ritossa (1962) who discovered the heat inducible chromosome puffs in the salivary glands of *Drosophila melanogaster* larvae. Subsequently, the puff-associated genes and proteins were identified initiating a rapidly expanding research field on HS. In bacteria, the HS response of *Escherichia coli* was the first to be characterized and the master regulator, the HS sigma factor σ^{32} , has been the first alternative sigma factor to be discovered in this organism. Later, many other bacteria have had their responses to high temperature investigated, and different control mechanisms have been revealed for the induction of HS genes, showing that even though the response is almost universally conserved, the molecular solutions for triggering gene induction can be quite distinct.

The sequential molecular events in the HS response include drastic repression of normal transcription and translation pathways, and activation of transcription of HS genes. The increased expression of HS genes is transient, and as the heat shock proteins (HSPs) accumulate and repair or prevent the damages caused by temperature stress through their chaperone and protease activities, the cells can return to nearly normal growth conditions, downregulating HSP gene expression. Both prokaryotic and eukaryotic cells have established a number of complex strategies to tightly control the transcription of HS genes under any given condition and here we will show some of these mechanisms of control. In addition, the function of HSPs will also be discussed.

Control of Heat Stress in Bacteria

Positive Control by Alternative Sigma Factors

The HS response in the Gram-negative bacterium *E. coli* is the best-characterized stress response in bacteria, and its regulation involves the use of minor sigma factors. The HS sigma factor σ^{32} , also called σ^H , was the first alternative sigma factor to be uncovered in *E. coli* and it controls the major HS regulon in this bacterium, coping with cytoplasmic protein damage. The second HS regulon is controlled by sigma factor σ^E and protects cells against extracytoplasmic stress or extreme HS in *E. coli*. A third regulon of the stress response has been identified more recently and is under the control of σ^N or σ^{54} . This regulon includes the phage shock operon (*pspABCDE*) and the small HSP encoded by the *ibpB* gene. Its regulation is not well understood and will not be discussed further.

The *E. coli* σ^{32} regulon

The σ^{32} regulon includes the major HSPs, encoded in operons or single genes, such as DnaK, DnaJ, GrpE, GroES, GroEL, ClpB, ClpX, ClpP, Lon, FtsH, and several other proteins. The most important chaperone machines such as DnaK/DnaJ/GrpE, ClpB, and GroES/EL, which protect the cell against cytoplasmic stress, belong to this regulon, as well as the proteases ClpXP, Lon, and FtsH, which degrade the irreversibly denatured proteins unable to be recovered.

Expression of these HSPs is rapidly enhanced upon temperature upshift due to the transient increase in the levels of σ^{32} , which occurs mainly by a higher rate of synthesis and temporary stabilization and activation of the HS sigma factor. The increased σ^{32} levels leads to the formation of σ^{32} -RNA polymerase (RNAP) holoenzyme, which transcribes the HS genes. The higher rate of synthesis of σ^{32} during HS is not due to increased transcription of the *rpoH* gene, which encodes the HS sigma factor, since its mRNA levels show only a small increase during temperature upshift. Even though the regulatory region of *E. coli* *rpoH* is rather complex, containing several distinct promoters, none of them is dependent on σ^{32} itself.

An mRNA thermosensor

The translational control of σ^{32} is mediated by the secondary structure of the *rpoH* mRNA. Deletion analysis of a translational fusion *rpoH-lacZ* revealed two regions near the 5'-end portion of the mRNA (regions A and B) involved in thermoregulation. Region A (6–20 nt from the AUG initiation codon) and region B (112–208 nt) form a secondary structure by base pairing, which includes the AUG preventing ribosome binding and translation of the mRNA at normal temperatures (Figure 1). At HS temperatures, the base pairing is destabilized enhancing the translation of *rpoH* mRNA.

Experimental evidences for such an RNA structure were generated by point mutations, deletion analysis, and structure probing correlating the RNA thermostability with the corresponding expression levels of σ^{32} . Furthermore, no evidence for the contribution of additional cellular factors was found suggesting the RNA structure itself as the molecular thermometer.

Control of σ^{32} stability

During normal growth temperatures σ^{32} is quite unstable, with a half-life of less than 1 min. However, a remarkable (at least eightfold) transient stabilization of the protein occurs immediately upon temperature upshift, which is responsible at least in part for the practically instantaneous induction of HSP synthesis. Degradation of σ^{32} can be carried out by several proteases, however, FtsH, an ATP-dependent metalloprotease located in the cytoplasmic membrane, was the first to be implicated in this process. In addition, the absence of FtsH causes complete stabilization of σ^{32} *in vivo*. Furthermore, the DnaK/DnaJ/GrpE chaperone machine seems to be involved in the turnover of σ^{32} , as absence of any of these proteins causes stabilization of the sigma factor at normal temperatures. However, *in vitro* degradation of σ^{32} by FtsH is not affected by any of the members of DnaK chaperone system, indicating that the effect may be indirect.

Role of DnaK in the turnoff of the HS response

Changes in the levels of DnaK affect not only the induction of the HS response in *E. coli*, but also the downregulation of the response. Cells with low levels of DnaK have a prolonged shutoff phase, whereas cells with high levels of this chaperone turn off the response more rapidly. Negative regulation of HSP gene induction by DnaK is mediated primarily by its direct association with σ^{32} , which leads to sigma factor inactivation and degradation by FtsH. This effect has been explained by the titration of DnaK by unfolded proteins during temperature upshift. When unfolded proteins are in excess relative to DnaK, DnaK dissociates from σ^{32} to

Figure 1 RNA thermometer controls the expression of *rpoH* gene. (a, b) Expression of *Escherichia coli* heat shock transcription factor σ^{32} , encoded by the *rpoH* gene, depends on five promoters differently modulated by three sigma factors (σ^{70} , σ^E , and σ^{54}) and the secondary mRNA structure is involved in its translational control. (b) At physiological temperatures (30 °C), the Shine–Dalgarno (SD) sequence, the AUG start codon, and two specific regions (A and B) in the coding region of the *rpoH* gene generate a secondary structure that represses the translation process. (c) Melting of the secondary structure at high temperatures (42 °C) permits ribosome access and translation initiation.

Figure 2 Induction and downregulation of the heat shock (HS) response in bacteria. (a) The direct DnaK association with σ^{32} leads to heat shock transcription factor inactivation and degradation by FtsH at normothermic temperatures. (b) Under HS stress, unassembled proteins are in excess, DnaK dissociates from σ^{32} and exerts its chaperone activity. The transcription complex RNA polymerase (RNAP)– σ^{32} is formed and transcription of HS genes increases. In *Escherichia coli*, the accumulation of chaperones, including DnaK, causes denatured proteins to acquire a correct folding, liberating DnaK to promote the negative regulation of σ^{32} and downregulation of the HS response. (c) In *Caulobacter crescentus*, changes in the amount of DnaK/DnaJ only affect the induction phase of the HS response. Reactivation of heat-inactivated σ^{73} (σ^{70} homologue) in this bacterium is dependent on ClpB chaperone activity, and the competition between σ^{32} and σ^{73} for the RNAP core seems to be the most important factor during the recovery phase.

exert its chaperone activity. Free σ^{32} then binds the RNAP core and transcription of the HS genes increases drastically, the *dnaKJ* genes among them. With the accumulation of DnaK/DnaJ and other HSPs, unfolded proteins are correctly folded, liberating DnaK to associate again with σ^{32} inactivating it, and leading to sigma factor degradation and the turn off of the HS response (Figure 2). Recently, the involvement of the chaperones GroES/EL together with the DnaK chaperone system in the regulation of the HS response in *E. coli* has been described, indicating that a cellular network regulates the activity of the HS sigma factor σ^{32} .

rpoH orthologues in other Gram-negative bacteria

Orthologues of *rpoH* have been described in many other proteobacteria of α , β , and γ subgroups, but not in the subgroups δ and ϵ or in Gram-positive bacteria. In most cases, only one *rpoH* gene has been found, but in some two or even three genes were characterized. In *Agrobacterium tumefaciens* and *Caulobacter crescentus*, bacteria from the α group, a single *rpoH* gene has been found. Interestingly, a marked increase in transcription is observed for the *rpoH* gene during HS in these bacteria, and the 5' portion of its mRNA is not predicted to form a secondary structure, unlike the situation observed in *E. coli* and other bacteria of the γ subgroup. The increased transcription observed for the *rpoH* gene in *Caulobacter* and *Agrobacterium* is due to the presence of an RpoH-dependent promoter. However, an essentially normal induction of HSPs was observed in *Agrobacterium* even with mutant strains unable to increase RpoH levels upon HS. These data indicate that controlling the activity rather than the amount of σ^{32} is the most important mechanism for the induction of the HS response in this bacterium. Furthermore, even though σ^{32} levels increase

transiently during HS, DnaK-mediated control of σ^{32} activity was demonstrated to play a primary role in the induction of the HSP synthesis. In addition, in *Caulobacter*, it was shown that downregulation of the response is independent of DnaK levels, whereas the chaperone ClpB is necessary for normal turnoff of HSP synthesis. This important role of ClpB in the shutoff of the HS response was suggested to be related to the capacity of this chaperone to renature the major *Caulobacter* sigma factor, names σ^{73} , in conjunction with the DnaK chaperone machine, which would then compete with σ^{32} for the RNAP core, leading to the recovery of normal protein synthesis (Figure 2(c)).

The root-nodulating bacteria *Bradyrhizobium japonicum* and *Sinorhizobium meliloti* contain three and two *rpoH* genes, respectively, which are regulated by distinct mechanisms. In *B. japonicum*, each *rpoH* gene is regulated differently. Transcription of *rpoH1* is HS inducible by an unknown mechanism, and *rpoH2* transcription decreases during HS, with both genes being transcribed from sigma 70-dependent promoters. The *rpoH3* gene is in a probable operon with two genes coding for a classical two-component regulatory system, with transcription initiating from a promoter similar to σ^{32} -dependent promoters. In addition, the distinct RpoH proteins transcribe different sets of genes. RpoH₂ seems to be essential for the synthesis of cellular proteins under physiological growth conditions, whereas RpoH₁, and probably also RpoH₃, are involved in their synthesis during the stress response. In *S. meliloti*, cells containing an *rpoH1* gene mutation are impaired in growth at 37 °C under free-living conditions and are defective in nitrogen fixation during symbiosis with alfalfa. In addition, expression of *rpoH1* increases upon culture entry into the stationary phase of growth, but not under HS conditions. Cells containing an *rpoH2* mutation have no apparent phenotype, and its expression increases later in stationary phase. Since both *rpoH1* and *rpoH2* are induced in stationary phase, the proteins they encode could play roles in the general stress tolerance that develops in starved cells.

The σ^E regulon

The second HS sigma factor of *E. coli* was identified from studies of *rpoH* transcription at extreme temperatures (45–50 °C). One of its promoters (P3) is activated at high temperatures and is dependent on σ^E , which places the σ^{32} regulon under the control of σ^E under extreme heat stress. The σ^E regulon is involved in protection against extracytoplasmic stress, with its members including a periplasmic protease DegP and a periplasmic peptidyl prolyl isomerase FkpA, among others. Even though σ^{32} is essential for *E. coli* growth only at high temperatures, σ^E is necessary at all temperatures. Besides heat and ethanol exposure, unfolded outer membrane or periplasmic proteins can induce the σ^E regulon. During normal growth conditions, activity of σ^E is inhibited due to its association with a membrane-bound anti-sigma factor, called RseA. Another periplasmic protein, called RseB, is also bound to RseA stabilizing the complex. Under extracytoplasmic stress, misfolded proteins bind to RseB, which releases RseA to be cleaved in its periplasmic domain by DegS. Additional proteolysis of transmembrane and cytoplasmic portions of RseA then frees the σ^E transcription factor, which directs the transcriptional response to extracytoplasmic stress. Transcription of *rpoE* is autoregulated, as the operon *rpoE-rseA-rseB* has a σ^E -dependent promoter. Thus, once the stress conditions are no longer present, σ^E is again bound to RseA and inactivated, and the response is turned off (Figure 3).

Orthologues of *rpoE*

Homologues of σ^E have been classified as extracytoplasmic function (ECF) sigma factors and are present in different numbers in distinct bacteria. Similarly to σ^E , they are usually found in an operon with the anti-sigma factor gene, which inactivates the ECF sigma factor by binding to it. Under stress conditions, the anti-sigma factor is inactivated by different mechanisms, liberating the sigma factor to bind the RNAP initiating transcription of their regulons. The ECF sigma factors are involved not only in HS but also in a variety of types of environmental stresses, including saline and osmotic stress, oxidative stress, antimicrobial biosynthesis, heavy metal exposure, and bacterial virulence. Interestingly, in alpha-proteobacteria certain ECF sigma factors, whose activation is regulated by a two-component system (sensor histidine kinase/ response regulator), have been shown to control the general stress response. In *C. crescentus*, for instance, the sensor histidine kinase PhyK is autophosphorylated in response to stress then transferring this phosphate group to the response regulator PhyR, which binds the anti-sigma factor NepR liberating the ECF sigma factor σ^T to transcribe the general stress response regulon.

Negative Regulation of HS Genes

In contrast to the positive regulation by alternative sigma factors observed only in proteobacteria, negative regulatory systems are more widespread in prokaryotes, typically involving repressor proteins that bind to *cis*-acting regulatory sites located in the 5' region of the genes encoding chaperones and proteases. Evidence for additional regulatory mechanisms transpired from the finding that several stress genes in *Bacillus subtilis*, a Gram-positive bacterium, including the *dnaK* and *groE* chaperone operons, remained heat inducible in a *sigB* mutant – the gene encoding an alternative sigma factor involved in stress responses. In addition, inspection of the corresponding promoter sequences revealed typical housekeeping promoters (SigA-dependent promoters) for the HS operons, and analysis of a temperature-sensitive *sigA* mutant revealed that *groESL* transcription is SigA-dependent. Transcription from vegetative promoters was subsequently demonstrated in a number of bacteria, and regulatory DNA elements were found in the promoter regions, being proposed as putative repressor-binding sites responsible for transcriptional repression under normal growth conditions. Presently, it appears as if negative control of HS genes is more prominent in eubacteria than positive regulation by alternative sigma factors. HS regulation by HrcA and CIRCE (controlling inverted repeat of chaperone expression), the repressor and

Figure 3 The periplasmic response to heat is regulated by σ^E . Under normothermic growth conditions, σ^E is inhibited by the anti-sigma factor RseA. RseB stabilizes the RsaA- σ^E complex in the absence of heat stress. Perturbations in OMP folding due to extreme heat stress lead to disruption of the RseA-RseB interaction. The inner membrane-anchored DegS protease cleaves RseA in its periplasmic domain, the membrane-embedded protease RseP (YaeL) cleaves RseA near the inner membrane, and the released cytoplasmic RseA fragment is further degraded by protease ClpXP. The transcription factor σ^E is released in the cytoplasm and interacts with RNA polymerase core enzyme to promote transcription of genes involved in OMP assembly and degradation.

its binding site, was the first to be characterized and this regulatory system is widespread in Gram-positive bacteria, proteobacteria, and cyanobacteria.

CIRCE/HrcA

A 9-base inverted repeat with a consensus sequence of TTAGCACTC-N₉-GAGTGCTAA was first noticed upstream of *groESL* and/or *dnaK* operons of mycobacteria, *Clostridium acetobutylicum* and *B. subtilis*. Initially thought to be exclusive to Gram-positive bacteria, this regulatory element is now believed to be one of the most conserved in nature. As it had been reported exclusively in association with *groE* and *dnaK* operons, it was named CIRCE. However, its presence was more recently detected upstream of some other HS genes indicating that this element can have a greater regulatory potential than initially expected.

CIRCE is frequently located in the DNA region corresponding to the 5'-untranslated region of the mRNA, but it can also be positioned upstream or overlapping the transcription start site. The variability in the position of CIRCE in conjunction with the observation that this element is able to heat-control transcription from a position upstream of the promoter indicates a role mainly of the DNA rather than of the mRNA level. A negative role for CIRCE in the expression of HS genes was proposed based on the observation that mutations in this element resulted in elevated transcription of the genes located downstream from it.

HrcA acts as a repressor

The elucidation of CIRCE as a potential repressor-binding site began with a search for the cognate repressor. Evidences showing that a deletion mutant in the first gene of the *B. subtilis* *dnaK* operon (*orf39*) resulted in elevated levels of *groE* mRNA and that regulatory mutants affecting *B. subtilis* *groE* and *dnaK* expression were mapped in *orf39* strongly suggested this gene as encoding the CIRCE cognate repressor, which was named HrcA for heat regulation at CIRCE. Subsequently, the binding of HrcA to CIRCE was investigated by gel shift assays, and it was shown that the presence of GroEL is important for HrcA to acquire its active repressor conformation, both *in vitro* and *in vivo*. These results led to the proposal of a GroEL titration model for the CIRCE/HrcA regulatory system. In this model, HS leads to depletion of the GroEL pool due to the necessity of refolding denatured proteins. This depletion would cause inactivation of HrcA and derepression of transcription of the chaperone genes regulated by the CIRCE/HrcA system. Once the levels of the chaperones increase, sufficient amounts of GroEL would be present in the cell and HrcA would be activated and capable of binding to CIRCE again, turning off transcription of *groE* and *dnaK* operons (Figure 4).

Interestingly, in certain proteobacteria including *A. tumefaciens*, *B. japonicum*, *C. crescentus*, and *Xylella fastidiosa*, both *rpoH* and CIRCE/HrcA are present regulating *groESL* operons, but in no other HSP gene. The *groE* genes are negatively controlled by HrcA at normal temperatures and positively regulated by *rpoH* during HS.

The repressor HspR

HspR is an autoregulatory repressor protein discovered initially in *Streptomyces*, a genus of the high G+C actinomycete bacterial group. The HspR repressor/operator system was later found in other actinomycetes including *Mycobacterium tuberculosis* and in *Helicobacter pylori* and *Aquifex aeolicus*. However, HspR is much less widespread than HrcA, in particular it is not found in any low G+C Gram positive as *B. subtilis*. HspR acts as a repressor by binding at the HspR-associated inverted repeat (HAIR) site (consensus sequence: 5'-TTGAY-N₇-ACTCAA-3') within the promoter regions of the genes and operons it controls. In *Streptomyces coelicolor*, studies *in vitro* and *in vivo* have provided evidences the DnaK functions as a corepressor of the HspR regulon, which is shown to include *lon* and the *dnaK* and *clpB* operons. Thus, DnaK negatively regulates its own expression. Although 17 genes were shown to be upregulated more than twofold in a *S. coelicolor* *hspR* disruption mutant, transcriptome and genome sequence analyses indicated

Figure 4 The activity of the repressor HrcA depends on the GroEL system. In the absence of heat stress, GroESL converts the HrcA protein into its active form. HrcA binds controlling inverted repeat of chaperone expression (CIRCE) regions on heat shock (HS) genes inhibiting the RNA polymerase holoenzyme access. During temperature upshift, unfolded proteins titrate the GroESL chaperone system, leading to an increase in the amount of inactive HrcA. HS gene transcription is induced leading to activation of repressor HrcA that binds to CIRCE turning off transcription of the HS operons.

that the above three transcription units are probably the only direct targets of HspR in this bacterium. Interestingly, in the genus *Streptomyces* besides the HspR/HAIR regulatory system, the HrcA/CIRCE system has also been described regulating the *groEL1/ES* operon and the *groEL2* gene, and the RheA repressor protein (which will be described below) negatively regulating the transcription of *hsp18* in *Streptomyces albus*. This is a clear example of multiple regulatory systems acting in conjunction to control HSP gene expression in bacteria.

The regulatory element ROSE

The *cis*-acting regulatory element repression of heat shock gene expression (ROSE) contains a conserved sequence of about 100 nucleotides in the 5'-untranslated region of multiple small HS genes including *rpoH* in several bacteria. The inhibitory effect of ROSE is based on experimental evidences that indicated this regulatory element as a putative site to bind to a repressor protein. Extracts from non-HS cells of *B. japonicum* retarded full-length ROSE in gel shift assays. However, a regulatory protein with a potential ability of binding DNA containing ROSE element was never isolated. In fact, computer calculations indicated that ROSE predicted to fold into a complex structure occluding both the Shine–Dalgarno (SD) sequence and the translation start site AUG, suggesting the possibility of ROSE acting as a RNA thermosensor similar to the *rpoH* thermometer. The thermoresponsive structures folded in the 5'-UTR region of mRNAs are known to control translation of HS and virulence genes in bacteria. The potential role of this RNA structure was determined by mutational studies with ROSE cloned upstream the *hspA*–*rpoH* operon from *B. japonicum*. Mismatches introduced into unpaired regions of the stem-loop IV of the thermometer structure were completely neutral, but when mismatches were introduced in the paired regions of the same loop, an increased expression of a translational *lacZ* fusion was observed. Besides this, compensatory mutations restored repression of translation. The correct function of ROSE thermometer depends on the presence of a conserved G residue opposite to the SD, its elimination made the thermosensor irresponsive to high temperatures. The G residue closes the loop of the thermometer by a weak GG base pair that breaks at elevated temperatures making the ribosome-binding site accessible to initiation of the translation process.

The repressor RheA

An open reading frame (*rheA*) located 150 bp upstream in the opposite orientation of the small HS gene *hsp18* participates in negative regulation in the Gram-positive bacterium *S. albus*. The small HSP, Hsp18, is involved with acquisition of thermotolerance in the bacteria of *Streptomyces* genera.

The *S. albus rheA*-null mutant displays high *hsp18* mRNA levels at physiological temperature. On the other hand, overexpression of the *rheA* gene restores repression of *hsp18* in *rheA* mutant cells. Curiously, the *hsp18* mRNA is translated only after temperature upshift, suggesting a posttranscriptional control to *hsp18* gene expression in this bacterium. One possible model for this posttranscriptional control involves changes in mRNA conformation as described for the ROSE element and the *rpoH* gene. Denaturation of the secondary structure of the mRNA would therefore lead to an increase in ribosome binding and translation initiation.

Two similar inverted–repeated sequences are present in the promoter region of the *hsp18* gene (GTCATC–N₅–GATGAC) and in the 5'-untranslated region of the *rheA* gene (GTCGTC–N₅–GATGAC), indicating that both the genes are controlled in a coordinated way and probably by the same regulator. In gel shift assays, when DNA/RheA sample was incubated under normothermic temperature, a shift was observed in the mobility of the DNA fragment. However, no complex formation was observed at HS temperatures. In fact, RheA is an autoregulatory protein and its activity is inhibited at elevated temperatures, but the temperature-induced derepression by RheA is reversible. At low temperature, RheA binds its target in the promoter region, preventing *hsp18* expression. At high temperature, RheA is inactivated derepressing the *hsp18* gene. Then, RheA acts as a cellular thermometer in *hsp18* expression, sensing increases in temperature and derepressing *hsp18* gene transcription.

CtsR

The CtsR regulon consists of three transcriptional units: the tetracistronic *clpC* operon containing *ctsR*, *mcsA*, *mcsB*, and *clpC* genes and two monocistronic *clpP* and *clpE* operons. The *clpC* and *clpE* genes code for ATPase subunits and *clpP* codes for a proteolytic subunit of the two ClpCP and potential ClpEP ATP-dependent proteases. McsA and McsB are kinases that act as modulators of CtsR. In Gram-positive bacteria, CtsR is a repressor that controls the class III HS genes, class I genes are regulated primarily by the repressor HrcA, class II genes are regulated by the alternative sigma factor σ^B , and the two-component system CsrS controls the class V genes.

The repressor CtsR is a dimeric protein that contains a classical helix–turn–helix DNA-binding motif, which binds to a highly conserved heptanucleotide direct repeat (A/GGTCAAAnAnA/GGTCAAA), located upstream of *clpP*, *clpE*, and the *clpC* operons. Besides this, CtsR contains two other functional domains: a dimerization domain (the first 24 domains) and the central glycine-rich region (aa 64–67) involved in heat sensing.

All three transcriptional units regulated by CtsR are preceded by two promoters each, *clpE* by two σ^A -dependent promoters and *clpC* and *clpP* operons by σ^B - and σ^A -type promoters. The dimeric protein CtsR binds the –35 and –10 regions of the σ^A promoter preventing the association of the σ^A RNAP holoenzyme to it.

At physiological temperatures (37 °C), the expression of CtsR maintains a certain steady-state level, which leads to a low expression of the genes from CtsR regulon. Upon exposure to heat stress, not only a rapid degradation of CtsR by ClpCP proteases occurs but also an induction in the expression of HS genes. ClpE was reported as a new independent type of the HSP100 ATPase belonging to the CtsR regulon in Gram-positive bacteria. ClpEP was found to destabilize CtsR after HS *in vivo*. Coherent with this, it was recently reported that a *clpE*-null mutant displays a significant delay of protein disaggregation and retardation of CtsR-dependent gene induction.

All the genes of *clpC* operon are involved in the regulation of the activity of CtsR. McsB is at the center of a network interacting with the McsA, ClpC, and CtsR. McsB is a tyrosine kinase, which utilizes a guanidine kinase domain, known only from eukaryotic kinases. McsB needs to be activated by McsA, which becomes concurrently phosphorylated by McsB. McsA activates the kinase activity of McsB that when phosphorylated causes the phosphorylation of CtsR and a stronger CtsR–DNA-binding inhibiting activity. On the other hand, ClpC inhibits the kinase activity of McsB. Upon HS *in vivo*, CtsR is degraded and this HS-induced degradation depends on the presence of McsA.

Bacterial HS Response Induced by Antibiotic-Stress

Pathogenic bacteria have the ability to persist in the human host and medical environment where they encounter an excess of stressors like heat shock and antimicrobials. Heat shock response activation by antimicrobials has been reported in different *Gram* negative multi drug resistant bacteria (MDR) such as *E. coli*, *Pseudomonas aeruginosa*, *Acinetobacter baumannii*, *Burkholderia cenocepacia* and in *Gram* positive bacteria such as *Staphylococcus aureus* and *Streptomyces coelicolor*. A large amount of recent data have shown that molecular chaperones clearly play important roles in bacterial stress tolerance, but their role in antibiotic tolerance is still starting to be clarified.

HS response induced by antibiotic in Gram Positive Bacteria

In *S. aureus*, a knockout in the *dnaK* gene increased the susceptibility of the methicillin-resistant strain COL to the antibiotics oxacillin and methicillin. Chaperones are known to be involved in responses to antibiotics because they are induced when the cell wall is subjected to antibiotic stress in *S. aureus*. On the other hand, ciprofloxacin treatment in *S. coelicolor* caused reduced levels of the chaperones GroESL and DnaK at both, transcript and protein levels. In a transcriptomic study of *S. coelicolor* (strain A3-2) in the presence of ciprofloxacin the *htpG* gene was up regulated. This increase is supposed to occur in compensation of the decrease in GroESL and DnaK proteins levels. The role of HtpG chaperone has not been clearly defined in bacteria yet. However, it is suggested that HtpG could become the primary folding mechanism under stress caused by antimicrobials, when other chaperones are down regulated. Despite the data mentioned above, recent proteomic studies for *S. coelicolor* indicated the down regulation of the chaperone HtpG and ClpB upon exposure to ciprofloxacin. In this bacterium, ClpB and DnaK belong to the same regulon, reflecting their functional cooperation.

HS response induced by antibiotic in Gram Negative Bacteria

Antimicrobial peptides (AMPs) are antibiotic agents commonly found in animals, plants and microorganisms, and they have been suggested as the future of antimicrobial chemotherapies. Resistant and susceptible strains of *E. coli* ATCC 8739 to the AMP named magainin I, were compared by proteomic analysis. The authors report the observation that alterations of DnaK and GroEL expression in the metabolism of resistant strains occurred only in a non-stress environment. The arousing decrease in the levels of the intact forms of the chaperones DnaK and GroEL and the increase of their forms with reduced molecular masses were also observed only in the magainin-resistant strains, showing that individual metabolic alterations could be occurring among the resistant strain group suggesting that in *E. coli* could take place posttranslational modifications induced by AMPs in the HSP group.

Quantitative proteomic was also used to compare the expression programs of two clonal isolates of *B. cenocepacia* retrieved from patient presenting chronic respiratory infection. The isolate IST439 was the first bacterium recovered while the clonal variant IST4113 was obtained after three years of persistent infection and intravenous therapy with ceftazidime/gentamicin antimicrobials. However, both isolates exhibited a MDR profile towards different classes of drugs. A higher content of the molecular chaperones ClpB, DnaK and GroEL was observed in the isolate IST4113 compared with IST439 and it is also consistent with higher robustness of isolate IST4113 against environmental stresses and in particular antibiotic-induced stress.

In the case of *A. baumannii* (ATCC 19606), cells pretreated for 30 min at heat shock temperatures (45 °C) proved to be more thermotolerant and resistant to aminoglycoside streptomycin than bacteria pretreated at physiological temperatures (37 °C). In addition, DnaK levels increased more than 4-fold after 1 hour of exposure to a subinhibitory concentration of streptomycin, and GroEL levels doubled. Incubation of a MDR *A. baumannii* RS4 strain in the presence of different antibiotics resulted in a significant increase in the production of DnaK mRNA and protein. A similar result was observed by comparative proteomics for isolates of *A. baumannii* under carbapenem stress, which increased the synthesis of three different chaperonins.

Multidrug-resistant *A. baumannii* strains have been considerably studied at nucleic acid sequence and proteomic level. The proteome of the multidrug resistant strain BAA-1605 was compared with the proteome of the drug-sensitive strain ATCC 17978. Not all stress-related proteins are more abundant in the MDR strain, but ClpA/B chaperone and DnaK were 7-fold and 2-fold higher in abundance in the MDR strain than in the drug-sensitive strain, respectively. In *P. aeruginosa*, for instance, both the aminoglycoside tobramycin and heat shock induce the expression of Lon protease AsrA mediated by the heat shock sigma factor σ^{32} . However, overexpression of the *asrA* transcript makes *P. aeruginosa* cells just moderately resistant to the aminoglycoside.

The reason for the connection between the heat shock response and aminoglycosides is the fact that this antimicrobial impacts cytosolic protein folding leading to accumulation of insoluble proteins in the cell. Overexpression of GroESL from *E. coli* (strain MG1655) reduced protein misfolding and rescued the membrane potential, cell growth and survival. In contrast, inhibition of GroESL expression increased aminoglycoside sensitivity allowing the collapse of the membrane potential abridging cell life. Overexpression of the DnaK/DnaJ/GrpE chaperone system increases survival, but less efficiently than the GroES/EL system because it does not promote growth of aminoglycoside-exposed bacteria. Thus, it is supposed that HSPs can eliminate unfolded proteins

targeting the atypical mistranslated polypeptides that are produced by aminoglycoside-disrupted ribosomes and that insert into and disturb bacterial membranes. Aminoglycoside-mediated membrane damage has been described and is supposed to be a key-step in the lethal activity of these agents. Then, elimination of atypical polypeptides would therefore reduce their toxicity to bacterial cells. In fact, HSPs help bacteria cope with early exposure to aminoglycosides (Figure 5).

HS Response in Archaea

HSPs

The three domains of life on Earth include the two prokaryotic groups, Archaea and Bacteria. The Archaea domain presents three phyla, Crenarchaeota, Euryarchaeota, and Korarchaeota. All of them are distinguished from Bacteria based on differences in tRNA and rRNA sequences, in the cytoplasmic membrane and cell wall composition, in the transcription and translation apparatus, and their restriction to unusual habitats. In addition, members of archaea present a general capacity to dominate or out-compete bacteria in niches in which chronic energy stress is a characteristic, including environmental stresses (temperature, acidity, and salinity) and low energy availability.

The ability to cope with environmental stress is essential to all microorganisms, including those thriving in extreme temperatures like hyperthermophiles archaea, they also have thermal limits and display a classic heat shock-response when thermally stressed. However, genome sequence information indicates that some archaea lack HSPs that were previously known to be ubiquitous in Eucarya and Bacteria. Hyperthermophiles archaea lack several HSPs, to name a few, HSP90, HSP70/DnaK, DnaJ, GrpE, HSP33, and HSP10 homologues. The minimal protein-folding machinery present in these organisms may represent a prototype of antistress systems in early life. However, it remains unclear whether archaea members use other proteins or proteases associated to resolubilize and eliminate the aggregates formed following stress by high temperature.

Despite the fact that not all archaea have DnaK or the other component of the KJE (DnaK-DnaJ-GrpE) chaperone system, chaperonins, also known as Hsp60 or GroEL, are present, in the genome of all archaea and their up-regulation is part of multiprotein complexes known as thermosomes during stress by heat shock. Thermosomes are constituted by large oligomeric ring containing 7–9 subunits that assist in the protein folding and other functions. These proteins are more similar to the type II chaperonins found in the eukaryotic cytosol than to the type I chaperonins found in chloroplasts, mitochondria and bacteria. However, some archaea species also possess type I chaperonin homologues.

Genome analysis in the archaea species has revealed that these organisms do not always contain *hsp70* or the other two genes of the chaperone machine triad, *hsp40* and *grpE*. Nevertheless, the full genome sequence of *Methanobacterium thermoautotrophicum* and *Methanosarcina mazei* S-6 demonstrates the presence of the genes from the Hsp70 chaperone machinery.

The amino acid sequence of the archaeal HSP70 resembles more the bacterial than the eukaryal counterpart. In addition, the activity of *M. mazei* HSP70 is enhanced by interaction with bacterial cochaperone DnaJ, but not by the eukaryotic homologue, indicating that archaeal *hsp70* gene may have been received from bacteria by lateral gene transfer. In addition, *in vitro* experiments demonstrated functional similarities between the *M. mazei* HSP70 and *E. coli* DnaK, but they do not present complete functional resemblance. *M. mazei* HSP70 functions as a chaperone in luciferase renaturation *in vitro*, and it requires bacterial-type chaperones like DnaJ and GrpE to perform its function. However, *E. coli* *dnaK* mutants were not complemented by the *hsp70* *M. mazei* gene.

Figure 5 Chaperone effects on bacterial survival during early aminoglycoside exposure. (a) Aminoglycoside uptake and binding to ribosome causing translational misreading. Misread polypeptides are encountered by chaperones acting in succession. Limiting chaperone capacity causes protein misfolding, membrane permeabilization, depletion of essential cytosolic functions and cell killing. (b) In contrast, chaperone availability (mainly GroESL) ensures protein folding and increased bacterial survival (KJ: component of DnaK-DnaJ-GrpE chaperone system).

In the thermoacidophilic archaeon *Sulfolobus sulfataricus*, Hsp20 gene is heat-inducible and the protein possesses chaperone activity and ability to recognize and bind unfolded proteins to prevent their aggregation in vitro. In addition, *S. sulfataricus* Hsp20 expression in an *E. coli* system protects the cells from thermic stress.

The *Crenarchaeota* species has a separate class of HSP60 chaperonins related to the eukaryotic protein and only distantly related to the highly conserved bacterial GroEL. As mentioned above chaperonins are organized into two groups: class I and class II. Class I is found in Eubacteria, mitochondria, and chloroplasts. Class II is found in Archaea and the eukaryotic cytosol. Class II chaperonins are oligomeric proteins that have two rings containing eight or nine subunits each. Some chaperonins are heat inducible, but others are regulated at low temperatures.

A Lon protease gene homologous to the bacterial *lon* gene was also identified in the Crenarchaeota *Archaeoglobus fulgidus* by sequence analysis, but the ATP-binding domain was absent in the predicted protein. In general, some HSPs are absent in members of the Crenarchaeota, although they are found in some members of the Euryarchaeota. Furthermore, transcription factors that control thermotolerance are missing in crenarchaeotal genomes.

HS Control in Archaea

Archaeal *hsp* genes respond to HS by an increase in the production of their monocistronic transcripts, as one would expect for stress genes. Maximum transcript levels are reached after longer exposures to high temperature than those that would induce a peak response in bacteria, in agreement with what is observed in eukaryotes.

The mechanism of transcription initiation for archaeal genes differs from those known to operate in bacteria and must involve factors that are not of a bacterial type, thus different from σ factors. In fact, transcription initiation in archaea closely resembles eukaryal class II transcription initiation and is mediated by a single RNAP and two general transcription factors, TATA element-binding protein (TBP) and transcription factor B (TFB). Archaeal cells do not have sigma factors or homologues of eukaryotic heat shock transcription factors (HSFs) or sequences similar to heat shock elements (HSEs), which will be described below, and this suggests that Archaea have evolved a unique mechanism to control the HS response, but the components involved in this process are not obvious until the present time.

The archaeal repressor Phr

Interestingly, in the hyperthermophiles *Pyrococcus furiosus* there is the first transcriptional repressor (Phr) characterized until now in Archaea that shows little similarity to eukaryotic or bacterial regulators. *P. furiosus* grows optimally near 100 °C and undergoes a heat shock response at 105 °C mediated in part by the repressor Phr. The N- and C-terminal domains in Phr exhibit bacterial and eukaryal features, respectively. In addition, Phr amino acid sequence displays 23% of identity to the human BAG domain. The conserved eukaryotic BAG proteins bind to the ATPase domain of HSP70 and regulate the chaperone activity. In spite the fact that no homologue to HSP70 is encoded in *Pyrococcus*, HSP60-like chaperonins and AAA⁺ chaperones are detected and could be potential binding targets of the BAG-like domain in Phr.

Phr exists as a homodimer and recognizes a nucleotide sequence overlapping the transcription start site of some HS genes (sequence consensus: 5'-TTTAnnnACnnnnnGTnAnnAAAA3'), thereby inhibiting RNAP recruitment. Phr does not affect binding of TBP and TFB to the promoter, but abrogates RNAP recruitment to the TBP/TFB complex at optimal temperature.

Three of the nine genes described to be regulated by Phr in *P. furiosus* are annotated as encoding conserved hypothetical proteins. Two of them have homologues in bacteria and archaea and only one has homologues just in bacteria. This finding suggests a lateral gene transfer from bacteria to *P. furiosus* genome. Another Phr target, is the gene encoding the enzyme myo-inositol-phosphate synthase that is involved in the production of the compatible solute di-myo-inositol-1,1'-phosphate (DIP). This protein has been shown to accumulate to high concentrations in the cytoplasm of *P. furiosus* at suboptimal growth temperatures and to stabilize proteins at extreme temperatures. The other proteins regulated by the repressor include a ferritin/ribonucleotide-like family and a heat shock inducible phosphoesterase that is supposed is involved in the synthesis of organic phosphates. In addition, Phr inhibits specifically cell-free transcription of its own gene, HSP20, and of an AAA⁺ ATPase. The *aaa⁺atpase* and *phr* mRNA levels are induced after HS and during stationary growth phase in *P. furiosus*, indicating that the transcription of these genes is also affected by general stress and starvation. By contrast, the levels of the protein Phr are only slightly elevated during heat stress. *In vitro* experiments have shown that at high temperature (103 °C) Phr loses its functional conformation. The dissociation of the protein from its operator sequence may account for the high increase of *phr* mRNA levels detected after temperature upshift. Then, in *Pyrococcus* there is a simple model for HS regulation: Phr binds promoter regions of HS genes at normothermic temperature inhibiting transcription by blocking RNAP recruitment. Subsequent release of Phr along with elevated temperatures leads to activation of HS genes.

VapBC in Archaea

VapBC (virulence-associated protein BC) proteins belong to toxin-antitoxin (TA) system and are thought to promote survival during environmental stress. TA system consists of an intracellular protein toxin co-expressed with a cognate protein antitoxin. The two component system genes are usually contiguous and encoded on the genome or plasmids. Cognate toxins are inactivated by antitoxin that is susceptible to cleavage by proteases due to its natively unfolded C-terminal domain. Free-toxins are able to modulate protein synthesis acting as ribonucleases. Protein expression in the cell is controlled by the concentration of stable toxin and unstable antitoxin. Three TA families are described in archaea: RebBE, Phd/Doc and VapBC. The VapBC family is the most abundant TA system among prokaryotic genomes and is present in high numbers in the archaea including hyperthermophiles and

thermoacidophiles. VapB is the unstable antitoxin and VapC is the stable toxin. VapC toxin has a PIN domain (PitN-terminal) which is suggestive of RNase activity. In the archaea *S. solfataricus*, for instance, VapC toxin appears to regulate abundance of its cognate antitoxin. In contrast, VapC transcript abundance is reduced when VapB is deleted. Apart from the above, the significance of the TA loci in the Archaea remains unknown at the moment.

Heat Stress in Eukaryotic Cells

In eukaryotes, many of the HSPs and molecular chaperones are represented as large gene families with functional homologues in each cellular compartment, including cytosol, nucleus, and specialized organelles, such as endoplasmic reticulum (ER), mitochondria, and chloroplasts. There are families of proteins for HSP100, HSP90, HSP70, HSP60 (which are restricted to mitochondria and chloroplasts), and HSP27/28. Among the questions still outstanding concerning this great number of proteins is to which extent the different homologues vary in their ability to carry out their various chores, such as preventing protein aggregation, maintaining the unfolded state necessary for protein transport among different cellular compartments, disaggregating protein aggregates, and regulation of the HS response.

HSP Families

The HSP100 family

The HSP100 protein family includes the HSP104 from yeast and ClpB from bacteria, which are required for induced thermotolerance to extreme temperatures. HSP104/ClpB belongs to the AAA + protein superfamily, which includes the 'ATPase associated with a variety of cellular activities' (AAA) proteins and Clp/HSP100 proteins. These two protein classes exhibit considerable sequence homology in their 'AAA' domains, which are important for ATP hydrolysis and oligomerization. Usually AAA + proteins form ring-shaped homohexamers, which drive the assembly and disassembly of macromolecular complexes by ATP-dependent remodeling of their substrates.

The main target of the proteins from the HSP100 family is protein aggregates, and they act together with HSP70 proteins as a bi-chaperone system (HSP104/HSP70 or ClpB/DnaK) in the refolding of aggregated proteins. The cooperation DnaK/HSP70 chaperone system in the disaggregation process was proposed to be either by acting sequentially after ClpB/HSP104 or simultaneously. Protein aggregates of reduced size, generated by ClpB/HSP104, could serve as substrates for DnaK/HSP70, which has a disaggregation activity toward small protein aggregates.

The HSP90 family

Concerning the HSP90 family, the abundance and essentiality for cell growth of HSP90 proteins, found in the cytoplasm and ER, suggests that they perform important biological functions in eukaryotes. However, the bacterial homologue HtpG is not found in many bacteria analyzed, and when present it is not essential for growth. Among the major HSPs, HSP90 is unique in its functions, since it is not required for the maturation or maintenance of most proteins *in vivo*. The majority of its identified cellular targets are signal transducers and cell cycle and developmental regulators whose conformational instability is relevant to their roles as molecular switches. Through low-affinity interactions characterized by repeated cycles of binding and release, HSP90 keeps these unstable signaling proteins poised for activation until they are stabilized by conformational changes associated with signal transduction. Studies of yeast illustrate the specificity of HSP90: at normal temperatures, reduction on HSP90 levels that have no apparent effects on cell growth or metabolism, but can completely abolish signaling through HSP90-dependent pathways. Conditions that cause general protein damage can divert HSP90 from its normal targets to other partially denatured proteins, and due to its dual involvement, HSP90 may link developmental programs to environmental contingency.

The HSP70 family

The HSP70 protein family is the best characterized and contains the largest number of members localized in many different compartments of the cell, including cytosol, mitochondria, and ER. The HSP70 is, by far, the most conserved protein in evolution. It is found in all organisms from archaea and plants to humans, and the prokaryotic HSP70 protein DnaK shares approximately 50% amino acid identity with eukaryotic HSP70 proteins. Functionally, the organellar HSP70s are better understood, having roles in protein translocation and folding. They are constituents of what is called the HSP70 (DnaK) chaperone machine, together with the co-chaperones HSP40 (DnaJ) and GrpE. The DnaK and DnaJ members appear to be bona fide chaperones: DnaK prefers to bind unfolded polypeptides and DnaJ binds to the more compact intermediate, termed molten globule. In some instances, the DnaK/DnaJ proteins appear to bind synergistically to an unfolded substrate and then hand it off to the second most important chaperone system formed by GroEL/GroES (HSP60/HSP10). The DnaJ and GrpE proteins dramatically regulate the otherwise weak ATPase activity of the DnaK partner, with DnaJ specifically accelerating the rate of hydrolysis of the DnaK-bound ATP and GrpE accelerating the ADP/ATP exchange by causing the release of DnaK-bound nucleotide.

The HSP60 family

The HSP60/GroEL chaperone machine consists of the GroEL (HSP60) and GroES (HSP10) family members, also called chaperonins. This chaperonin system is restricted to eubacteria, mitochondria, and chloroplasts. The GroEL protein appears to bind unfolded polypeptide substrates when present in the compact molten globule state, which corresponds to a proposed folding intermediate that still exhibits hydrophobic groups. The GroES protein has a pivotal role in substrate maturation by coordinating the ATPase activity of the GroEL subunits. The GroEL subunits are arranged as two stacked heptameric rings with a central cavity where folding takes place. The GroES subunits form a single heptameric ring that binds to one of the GroEL rings regulating its function. ADP is tightly bound to the subunits in the ring adjacent to GroES and with lower affinity in the opposite ring. Unfolded protein binds to GroEL ring opposite to GroES and triggers ADP dissociation from GroEL subunits. This in turn results in the release of GroES. ADP-ATP exchange weakens the affinity for the bound protein. GroES rebinds GroEL in the ATP state and may cover the ring that contains the bound substrate. Cooperative ATP hydrolysis releases the substrate protein for folding in the ring cavity. GroES binding becomes stabilized in the regained ADP state, and partially folded protein may reassociate for another round of interaction. Even though no direct homologues of HSP60 exist in the cytosol, a different class of chaperonins was described in thermophilic archaeobacteria (TF55) and found to have homology with the TCP-1 protein present in the cytosol of most eukaryotic cells forming a heterooligomeric ring structure complex named TriC. Although initially proposed as specialized for the folding and assembly of cytoskeletal proteins, it is now becoming clear that TriC has a more general chaperonin function.

The HSP27/28 family

An interesting aspect of the HSP27/28 class of proteins, also called small HSP (sHSP), is its structural and functional similarity to that of α -crystallins. They encompass a large number of related proteins that share some structural features common to the lens protein α -crystallin and are present in virtually all organisms. Analyses of several members of this family of proteins have led to the conclusion that in unstressed cells each sHSP has its own tissue-specific expression and particular intracellular localization. In contrast, during stress, most of the sHSPs analyzed are expressed in every cell and at least some of them were demonstrated to have protective functions. This indicates that they belong to the stress-induced machinery that protects against and/or repairs cellular damages. In fact, it has been shown that sHSPs of *E. coli* cooperate with ClpB and the DnaK system in reversing protein aggregation.

Proteases induced by HS

Many HSPs are proteases or makeup components of a protease system. This indicates that when the chaperone activities of the HSPs are not sufficient to renature the heat-denatured proteins, the proteolytic systems of the cells act by degrading them. In eukaryotes, the bulk of the ATP-dependent proteolysis is carried out by the ubiquitin system. In this system, polypeptides to be degraded are covalently attached to ubiquitin, which is an extremely conserved HSP. In addition, many of the ubiquitin-conjugating enzymes are also under HS or stress regulation. The degradation is mediated by the 26S proteasome, a large machine composed of two different complexes. The 20S core complex forms a hollow cylinder that is composed of four heptameric rings, which harbor the proteolytic active sites in its interior chamber. The substrates need to be unfolded and translocated before they can reach the proteolytic chamber. This task is executed by the 19S complex, which is located at either end of the 20S proteolytic complex. The base of each 19S complex contains AAA+ proteins that promote the ATP-dependent unfolding and threading of substrates into the proteolytic chamber of the 20S complex.

In prokaryotes, proteolysis of misfolded proteins is mediated by proteasome-like machines, which also consist of an ATPase module (i.e., ClpA and ClpX), and a proteolytic component, which is either covalently attached (i.e., Lon) or diffusible (i.e., ClpP). The peptidase ClpP of *E. coli* does not exhibit sequence homology to the subunits of the eukaryotic 20S complex. However, it forms a structure of similar architecture, consisting of two heptameric rings that generate a barrel-shaped proteolytic core with active sites hidden in an interior chamber. Access to these sites is controlled by narrow pores, which do not allow the passage of folded polypeptides. Substrate unfolding and translocation is mediated by various HSP100 proteins (i.e., ClpA), which associate with either end of the ClpP core. Recently, it has been observed that eukaryotic cells exhibit homologues of the Lon protease mitochondrially located.

Control of HSP Gene Expression in Eukarya

The HS response in eukaryotic cells is positively controlled at the transcriptional level by the ubiquitous HSFs that bind to arrays of 5-bp DNA consensus element nGAAn (HSEs) in the HSP gene promoter regions. A single gene (*HSF1*) encodes the HSF in the yeast *Saccharomyces cerevisiae* and in other eukaryotic microorganisms, whereas three to four different HSFs can coexist in plant, avian, and mammalian cells. However, HSF1 is the master regulator in vertebrates. *Hsf1*-knockout mouse and cell models have revealed that HSF1 is a prerequisite for the transactivation of HSP genes, maintenance of cellular integrity during stress and development of thermotolerance. All HSFs share common structural motifs, including a conserved DNA-binding domain, a trimerization domain, and a C-terminal transactivation domain, but are quite variable between species. Nevertheless, examples of functional interchangeability of HSFs from organisms as diverse as yeast, fruit, fly, and man have been demonstrated.

The HSF is synthesized constitutively in all eukaryotic organisms, its activity, however, is regulated post-translationally. Furthermore, there is diversity in the mechanisms of regulation of HSF activity. For example, under nonstressed conditions,

metazoans sequester the majority of HSF as chaperone-bound monomers within the cytoplasm. Upon HS, HSF monomers undergo an intramolecular rearrangement that allows HSF subunits to trimerize. HSF trimers then enter the nucleus and bind DNA at the HSEs, activating transcription of the HSP genes. Despite the apparent simplicity, transcriptional activation is not a necessary consequence of DNA binding. Treatment of human cells with salicylate induces HSF to trimerize and bind DNA but not to activate transcription. This suggests that there are at least two activation steps for metazoan HSF, one of which occurs subsequent to DNA binding. In fact, the DNA-binding and transactivation capacity of HSF1 are coordinately regulated through multiple post-translational modifications (including phosphorylation, sumoylation and acetylation), protein-protein interactions and subcellular localization. HSF1 also has an intrinsic stress sensing capacity, as both *D. melanogaster* and mammalian HSF1 can be converted from a monomer to a trimer *in vitro* in response to thermal or oxidative stress. There is strong evidence that HSF1 interacts with multiple HSPs at different phases of its activation. Trimeric HSF1 can be kept inactive when its regulatory domain is bound by a multi-chaperone complex containing HSP90. Elevated levels of both HSP90 and HSP70 negatively regulate HSF1 and prevent trimer formation upon heat shock. The negative feedback from the end products of HSF1-dependent transcription (the HSPs) provides an important control step in adjusting the duration and intensity of HSF1 activation according to the levels of chaperones and presumably the levels of nascent and misfolded peptides. Furthermore, evidence is accumulating that HSFs are very versatile transcription factors that, in addition to protecting cells against proteotoxic stress, are vital for many physiological functions, especially during development. Genome-wide gene expression studies have revealed that numerous genes not classified as HSP genes or molecular chaperones are under HSF1-dependent control. Although mice lacking HSF1 can survive to adulthood, they exhibit multiple defects, such as increased prenatal lethality, growth retardation and female infertility.

HSF1 from *S. cerevisiae* and *Kluyveromyces cerevisiae* (but not HSF1 from *Schizosaccharomyces pombe*) behaves differently from metazoan HSFs. Budding yeast HSF1 trimerizes and binds to promoters before stress. Nonetheless, upon HS, the level of HSF1-dependent transcription is enhanced. This suggests that yeast HSF1 can exist in two conformations – an unstressed ‘low-activity’ conformation and a stressed ‘high-activity’ conformation. *S. cerevisiae* HSF1 regulates transcription under normal physiological conditions as well as under different stress conditions, including heat, oxidative stress, glucose starvation, and pH, and it is essential for cell viability. The genes targeted by HSF1 encode proteins that function in a broad range of biological processes, including protein folding and degradation, detoxification, energy generation, carbohydrate metabolism, and cell wall organization. HSF1 is phosphorylated concomitant with its heat shock-induced activation, and this covalent modification is intra-molecularly controlled by two domains of the protein: CE2 and CTM. The CE2 region functions negatively to restrict the activity of HSF1 at low temperature and/or to convert the protein from an active to an inactive form. The CTM domain is required for extensive phosphorylation, but this requirement is bypassed in an *hsf1* mutant that lacks CE2, suggesting that the CTM domain alleviates the repressive effect of CE2 with respect to hyperphosphorylation. In addition, CTM regulates the activating ability of HSF1 and thereby affects recruitment of the transcription machinery. Cooperative protein–DNA and protein–protein interactions are important for fine-tuning transcriptional levels. The cooperative binding of HSF1 molecules to the HSEs is connected with the binding affinity to DNA and the strength of transcriptional activation.

Sensing the stress

In metazoans, HSPs and co-chaperones are assembled into multi-chaperone complexes to regulate HSF1 activity. HSP90-containing multi-chaperone complexes appear to be the most relevant repressors of HSF1 activity. Because HSP90-containing multi-chaperone complexes interact not only with HSF1 but also with nonnative proteins, the concentration of nonnative proteins can influence the assembly on HSF1 of HSP90-containing multi-chaperone complexes that repress activation, and may play a role in inactivation of HSF1.

Since yeast HSF1 is under negative regulatory control in the absence of stress, a model similar to the one in metazoans, where in the basal state HSF1 would be tied up with HSPs in a regulatory loop was investigated. This model however has been challenged by the observation that overexpression of Ssa2, one of the HSP70 homologues highly induced by HS in yeast, and thus a prominent candidate molecule in this feedback regulation, did not inhibit the HS response. Nevertheless, a role for HSP70 proteins in the down-regulation of the response cannot be discarded. In contrast, evidences were provided indicating that in *S. cerevisiae* and in *D. melanogaster* HS and oxidative stress can act directly on HSF1 by causing conformational changes capable of inducing its

Figure 6 Activation of HSF1 during heat stress in budding yeast. In yeast, HSF1 trimerizes and binds to HSE in the HS gene promoters before stress, but it remains in a low-activity form, probably inhibited by HSP70 or other chaperones at normal temperatures. During heat shock and in the presence of high levels of the chemical cochaperone trehalose, HSF1 undergoes hyperphosphorylation and conformational changes and becomes active producing a dramatic increase in the expression of HSP genes.

activation. In addition, it has been shown that the transcriptional activity of HSF1 during the HS response depends on trehalose levels in *S. cerevisiae*. Strains with low levels of the disaccharide trehalose have a diminished transcriptional response to HS, while strains with high levels of trehalose have an enhanced transcriptional response to HS. The enhanced transcriptional response does not require the other heat-responsive transcription factors present only in yeast, Msn2 and Msn4, but is dependent upon heat and HSF1. In addition, the phosphorylation levels of HSF1 correlate with both transcriptional activity and the presence of trehalose. These *in vivo* results support a new role for trehalose (which was previously known to be correlated with tolerance to adverse conditions in yeast, and suggested to act as a chemical co-chaperone), where trehalose directly modifies the dynamic range of HSF1 activity and therefore influences HSP mRNA levels in response to stress (Figure 6).

Even though the HS response has been better characterized in *S. cerevisiae*, many studies with heat stress have been carried out with other fungi and a number of different eukaryotic microbes. Presently, genomic and postgenomic tools, which have become available for high-throughput studies in several microorganisms, will certainly improve significantly our knowledge of HSP function and control in these organisms.

Final Remarks

For a variety of microbial pathogens, the expression of HS genes has been observed to be upregulated following host cell infection. Concurrent with this fact is the observation that HSPs are immunodominant antigens for a number of infectious organisms including bacteria, fungi, parasites, and protozoa. However, the exact role of HSPs during infection has not been clearly demonstrated yet.

For instance, studies with parasites and protozoa revealed that surface-expressed HSP90 is immunogenic in Chagas' disease, ascariasis, leishmaniasis, toxoplasmosis, *Trichinella spiralis*, and infection due to *Schistosoma mansoni*. In addition, *Trypanosoma cruzi* HSP90 can functionally complement yeasts, and its inhibition by the HSP90 inhibitor geldanamycin demonstrated that it was essential for cell division, as epimastigotes were arrested in the G1 phase of cell cycle. Recombinant *Leishmania* HSP90 and HSP70 were recognized by sera from patients with visceral leishmaniasis but not by Chagas' disease patients. HSP90 inhibitors led to growth arrest and the differentiation from the promastigote to amastigote. HSP70 and HSP83 have been suggested as distracting the immune system to a nonspecific activation of immune cells leading to immunosuppression.

In pathogenic fungi, similar results were found and this knowledge has been used in novel therapies against these microorganisms. For instance, the immunodominance of HSP90 in patients who survived disseminated candidiasis and invasive aspergillosis made this molecule a natural target for immunotherapy. In addition, immunization with a membrane fraction from *Candida albicans* containing HSP90 in combination with fluconazole protected mice from infection.

Finally, the involvement of HSPs in a number of human diseases including cancer and neurodegenerative disorders, as well as aging, gives further importance to the studies of these universally conserved proteins.

Glossary

Chemotaxis Chemotaxis serves as a navigation system for bacteria allowing them to temporally detect chemical gradients and respond. It works by biasing the direction of rotation of the flagellar motor. Additional forms of taxis – towards light and oxygen – work similarly.

Flagellar filament The semi-rigid helical flagellar filament (10–15 μm in length) serves as a propeller. It is polymerized from subunits called flagellins.

Flagellum The rotating bacterial propulsive organelle called the flagellum is composed of the flagellar filament, the hook basal body, and the motor. Cells can have a single flagellum or multiple flagella, inserted at one or both ends of a cell (polar) or around the cell body (peritrichous or lateral).

Hook basal body This structure, composed of rings and rods, serves as the rotating central drive shaft.

Motor The reversible motor transduces the chemical energy of membrane potential to rotate the hook basal body-propeller in a clockwise or counterclockwise direction via stator-rotor interactions.

MS ring The foundational ring for the flagellar structure, the MS ring, serves as the mounting plate in the cytoplasmic membrane for basal body and C ring assembly.

Rotor The core of the rotor is the switch complex and MS ring.

Stator (or torque generator) A multimeric complex of two proteins form the ion-conducting stator, which is anchored to cell-wall peptidoglycan. The passage of ions through a channel in the stator is coupled to generation of torque through electrostatic interactions of the stator with the switch complex to drive rotation. The best characterized stators, MotA₄B₂ and PomA₄B₂, use protons or sodium ions, respectively.

Surface sensing and mechanosensing The flagellum is an organelle of locomotion and also serves as a sensor of environmental conditions, including external load such as viscosity and contact with a surface, sodium concentration, ion motive force, and pH. Signal reception by the flagellum can be transduced to remodel motor configuration and/or gene expression.

Surfactants or wetting agents Molecules can be secreted or extracted from the surface by the organism to aid swarming motility by reducing surface tension or increasing wetness.

Swarming Flagellar propelled translocation on surfaces.

Swimming Flagellar propelled translocation in aqueous environments.

Switch complex (or C ring) Mounted at the cytoplasmic face of the basal body on the MS ring, the switch complex interacts with the stator to participate in torque generation. In addition, the chemotaxis system interacts with the switch complex to modulate the direction of motor rotation.

Flagella and Motility

Motility is a successful survival strategy for many organisms, and flagellar-propelled motility is a particularly outstanding mode of locomotion for a bacterium. Flagella allow bacteria to swim through dilute aqueous environments or to swarm in highly viscous conditions and over surfaces. The flagellum, which acts like a propeller, is powered by a rotary motor capable of turning the flagellum at very fast speeds. Rotation speed in liquid has been clocked at ~ 300 revolutions per second for *Escherichia coli* and >1700 revolutions per second for *Vibrio alginolyticus*. Such speeds produce swimming velocities of ~ 30 microns per second for *E. coli* and more than 100 microns per second for *Vibrio* species. The predatory *Bdellovibrio bacteriovorus* attacks other bacteria using high-speed collisions and swims at ~ 160 microns per second. On surfaces, flagellar-assisted motility allows bacteria to rapidly swarm in groups, sometimes achieving motility as fast as 10 mm per hour on agar medium. When coupled with a central navigation system (i.e., chemotaxis), flagellar rotation can be adapted to allow bacteria to move towards favorable environments and away from toxic conditions.

Considering that a bacterium is $\sim 2 \mu\text{m}$ in length, flagellar-assisted movement is very fast. To achieve these speeds, the architecture of the flagellum is highly complex (Fig. 1). It contains about 30 different proteins, and the amount of each protein varies from ~ 10 to more than 20,000 molecules. Assembly of the flagellum involves a dedicated type III secretion export apparatus. Proteins are secreted through a hollow, central axial structure and assembled in an ordered fashion beginning with the MS ring in the cytoplasmic membrane, followed by other components of the basal body, the hook, and finally filament subunits to make the propeller.

Fig. 1 Key parts of the flagellum. The flagellum works like a propeller (brown) that is turned by a central drive shaft, which is made up of the hook basal body (green) and the switch complex (blue). The type III secretion export/assembly apparatus (light blue pentagon) processively transports flagellar components, which polymerize at the growing distal end. Multiple stators encircle the rotor (one shown in orange). Ion flux (red circles) through the stator is coupled to rotation via electrostatic interactions between the stator and the switch (asterisk). The stators are stabilized via dynamic interaction with peptidoglycan. For some types of flagella, additional stabilization of the rotor can be provided by auxiliary proteins such as MotX and MotY (not shown).

Here, we briefly describe the working parts of the flagellar machinery, torque generation, and accessory elements adjusting movement. In addition to acting as propellers, flagella serve as environmental sensors, informing bacteria of surface contact. The underlying themes of flagellar-assisted propulsion are great structural diversity and superb adaptability. Swimming and swarming motility allow bacteria to navigate varied and changing environments; thus, these forms of locomotion play key roles in bacterial survival and colonization.

The Propellers

The propellers are hollow, semi-rigid helical filaments (~20 nm diameter and 10–15 μm or about 3–10 times the cell body in length). The filaments are composed of single subunits (called flagellins) or mixtures of subunits that self-assemble; these flagellins can be modified by phosphorylation or glycosylation. The flagellar filaments can be naked or protected by an outer membrane sheath, which may provide immune evasion and enhance adhesion. Flagella can be located at one or both poles, occurring as a single, polar flagellum or multiple polar tufts of flagella. They can be placed singly at the side of a uniflagellated cell. Or, peritrichous (also called “lateral”) flagella can be multiply arranged around the cell body. Sometimes the filaments are located in the periplasm, which is the case for the Spirochetes: Rotation of these periplasmic flagella turns the spirochete cell body into a screw. Thus, the structural design and arrangement of flagella on the cell body are tremendously varied. Additionally, elegant regulation links flagellar gene expression to morphogenesis and precisely controls flagellar filament assembly, length, number and placement on the cell body. These elements are described in more fascinating detail elsewhere in this series.

The Hook Basal Body (HBB)

The hook basal body serves as the central drive shaft connected to the propeller. The HBB is embedded in the cell membrane and consists of rods and rings (the basal body) and a flexible linker (the hook) to which the propeller is attached. Some of the rings serve as bushings for the rods to pass through the peptidoglycan layer and outer membrane (the P and L rings); other rings are integrated structurally into the rotor, e.g., the MS ring, which is the first element to be assembled. The C ring and the flagellar export apparatus are recruited by the MS ring, at which time the structure becomes competent for sequential secretion and assembly of the remainder of the basal body, hook, and filament.

The Stators

First detected in the cytoplasmic membrane by freeze-fracture electron microscopy, the stators encircle the flagellar basal body like studs (Fig. 2(A)). Each stator contains four copies of MotA and two of MotB (or their homologs); they form the ion-conducting channel complex (MotA₄MotB₂) that utilizes ion flux to induce the conformational changes that drive flagellar rotation. During force generation, the stators are transiently anchored to the cell wall via a peptidoglycan-binding domain in the C-terminus of MotB. Each stator functions independently to generate force. For *E. coli*, a single torque generator is sufficient to rotate the flagellum under conditions of low load, and the number of stators surrounding the rotor increases with increasing load on the flagellum to a

Fig. 2 The diversity of the flagellar torque generators. (A) MotA₄B₂ complexes work as stators (red hexagons) surrounding the rotor and dynamically exchange (indicated by arrows) with a pool in the membrane. Each stator complex works independently to conduct ions (usually sodium ions or protons) through a channel to generate force. Although a single stator is sufficient to rotate the flagellum in liquid, increasing stator number increases torque delivered at the rotor to drive greater speed and/or rotation under conditions of higher load (e.g., viscosity). The *E. coli* rotor accommodates ~11 stators, whereas the high-torque rotors of some bacteria have wider scaffolding rings allowing more stators to be docked. (B) Some flagella are powered by dual motors that use different energy sources, e.g., H⁺ (purple) or Na⁺ (red) powered torque generators. The number and kinds of stators docking at the rotor can be affected by environmental conditions such as viscosity, pH, and sodium concentration. Thus, environmental conditions influence motor configuration and performance. (C) Accessory proteins (gold) can alter rotation by changing direction of rotation (chemotaxis), preventing rotation (braking), or by interfering with stator-rotor interaction (clutching). These features can bind to the switch complex in the rotor (e.g., CheY or EpsS) or to the stator (e.g., MotI or FlgZ). The activity of some of these proteins is controlled by phosphorylation or the second messenger c-di-GMP.

maximum of ~ 11 . Dynamic assembly of the stators at the rotor results in rapid turnover and exchange of stators at the rotor through diffusion with a pool in the cytoplasmic membrane.

Fuel Sources

The power that fuels rotation is derived from the transmembrane potential of specific ions. The proton motive force is used by *E. coli* and *Salmonella enterica* to power MotAB-type torque generators; whereas the sodium motive force drives the PomAB torque generators of the marine *Vibrio* and the MotPS units of *Bacillus* species. More exotic motors can use K^+ , Li^+ , or Rb^+ as the motor driving force.

Torque Generation by Stator-Rotor Interactions

The rotary motor turns the helical flagellar filament by coupling ion flux through the MotA₄B₂ complex to rotation via specific electrostatic interactions between charged amino acids in the MotA protein of the stator and the FliG protein in the switch complex of the rotor. The switch complex is mounted on the base of the MS-ring of the basal body in the cytoplasm. It contains multiple copies of three proteins (FliG, FliM, and FliN) and is essential for torque generation and motor directional switching, which is the basis of chemotaxis.

The generation of torque for rotation involves stator docking at the rotor, stator anchoring to peptidoglycan, and opening of the ion channel in the stator to permit ion flux. The sequence of these events is currently unclear – e.g., whether channel opening is predicated by stator docking at the rotor and/or by peptidoglycan (PG) binding. Atomic force microscopy has shown that sodium flux induces structural transitions in the PG-binding domain of *B. subtilis* MotPS, and this conformational change results in docking of the stator with FliG in the switch complex, ion channel opening, and torque generation. However, the sequence of these events may differ for different kinds of motors. Crystal structures, nuclear magnetic resonance, and small angle X-ray scattering studies are providing insight into these steps.

The structure of some motors is more complex than the MotAB-type. The epsilon proteobacteria like *Campylobacter jejuni*, *Wolinella succinogenes*, and *B. bacteriovorus* have high-torque motors with ~ 17 stator complexes surrounding the rotor. These large numbers of stators are accommodated by wide-diameter, disk-like structures with periplasmic rings. Thus, additional power is achieved by more stators at a greater distance from the driveshaft. Stator occupancy in these bacteria is normally high (i.e., not responsive to load as for the *E. coli* motor). Since power output is not dependent on stator recruitment, this configuration allows for very fast swimming speed in liquid and immediately available torque to power motility in viscous environs.

PomAB motors, which power the high-speed rotation of the *Vibrio* polar flagellum, require auxiliary parts (MotX and MotY) that are essential for torque generation. MotX and MotY form an extra ring structure (T ring) around the basal body below the peptidoglycan and are required for proper stator rotor engagement. Another ring structure (H ring) aids MotX and MotY assembly. MotX interacts with PomB and MotY; MotY interacts with the rod of the basal body and peptidoglycan. These motor proteins are not specific to sodium-type motors. *Shewanella oneidensis* MR-1 uses MotX and MotY for both Na^+ and H^+ driven motility. In addition to aiding high speed rotation in low load situations, MotY plays a critical role in some types of motors under conditions of high load such as for the swarming motility of *Vibrio parahaemolyticus* and *Pseudomonas aeruginosa*. Thus, by contributing an additional peptidoglycan anchoring domain to the motor structure, MotY (by itself or along with MotX in some motors) plays a key role in stator stabilization or stator/rotor docking under conditions when more torque is required to power rotation.

Dual Motors

Some bacteria have multiple kinds of stators that work at the same rotor (Fig. 2(B)). For example, *Bacillus subtilis* and alkaliphilic *Bacillus* species possess dual stators that operate over a wide pH range and using different power sources. In most conditions, the H^+ -type MotAB motor of *B. subtilis* drives motor performance and enables fast swimming speeds, but input by its Na^+ -type MotPS stator contributes to motility at high pH, elevated salt, and high viscosity. Similarly, *S. oneidensis* uses its Na^+ -type PomAB stators to power rotation when Na^+ is high; whereas, MotAB-type stators aid its motility in low Na^+ conditions. *P. aeruginosa* has dual motors and these seem to work optimally under conditions of different load (liquid versus surface translocation). Artificial hybrid fuel motors have been constructed in *E. coli* by co-expressing proton and sodium-driven motors. This hybrid motor adapts to the prevalent ion gradient and removal of that gradient leads to dissociation from the rotor and stator swapping.

Widespread genome sequencing has revealed that many bacteria possess multiple MotAB homologs. Although it is mostly unknown whether all these motor genes are functional, it seems likely that the torque generators they encode function under different environmental conditions. Thus, dual motors powering a single rotor can each have particular contributions under different conditions. Stator selection at the rotor can be the result of abundance of motor parts created by transcriptional control. But also, the type or number of stators docking at the rotor appears linked to the capacity to generate torque. For example, the number of rotor-docked stators is dependent on sodium concentration and ion flux for the *Vibrio* sodium-driven PomA₄B₂ torque generators.

Performance Enhancing Features: Dual Flagellar Systems, Flagellar Number Regulation, and Lubricants

In addition to bacteria that possess dual motors powering the same flagella, bacteria like *Aeromonas*, *Azospirillum*, *Photobacterium*, *Shewanella*, and *Vibrio* species have two flagellar systems with dedicated motors for each system. Marine *Vibrio* use sodium-powered polar flagella for swimming and proton-driven lateral flagella for swarming (Fig. 3). *Aeromonas hydrophila* is particularly well equipped for motility in differing conditions: One type of stator complex drives its lateral flagella used for swarming while two other types of stator complexes utilize sodium to power the polar flagellum under high and low sodium ion concentrations. Each of the dual flagellar systems is often superior for movement under specific conditions and used exclusively for that purpose (i.e., polar organelles for swimming and lateral organelles for swarming).

Alternatively, the secondary system can aid navigation. *Shewanella putrefaciens* produces two kinds of flagella: A single polar and a 1–2 lateral flagella. The polar system is the main propulsive organelle for this organism; however, the lateral flagella aid movement in soft agar by decreasing the tumbling turning angle, which results in directional persistence of the cell trajectory and increased spreading into the environment.

Simply having more of the same kind of flagella to power movement facilitates swarming. *Proteus mirabilis* greatly increases flagellar number (>100-fold) to improve performance and rapidly propel swarming translocation over a surface. Some other bacteria more modestly increase flagella production during swarming (including *Bacillus*, *Pseudomonas*, *Salmonella* and *Serratia* strains).

Lubricants such as slime and wetting agents can play a role promoting flagellar-assisted motility on surfaces. Many swarming-proficient bacteria secrete biosurfactant-like molecules that aid motility by reducing surface tension. These include the glycolipid rhamnolipids of *P. aeruginosa* or the lipopeptides surfactin and serrawettin produced by *Bacillus* and *Serratia* species, respectively. Flagellar rotation and directional switching of the flagella may also mechanically extract liquid from agar to facilitate swarming.

Fig. 3 The dual flagellar systems of *Vibrio parahaemolyticus*. Some bacteria possess two flagellar systems dedicated to swimming or swarming. (A) A single, sodium-powered sheathed polar flagellum propels *V. parahaemolyticus* in liquid; (B) whereas on surfaces, cells differentiate into long, swarmer cells with numerous lateral flagella and move in groups. These flagella are powered by proton-driven motors. Cell width in each micrograph is $\sim 0.5 \mu\text{m}$. Note that cell body elongation or hyperflagellation are not required characteristics of swarming for many bacteria. The electron micrograph in (A) is of cells grown in liquid and stained with 1% uranyl acetate; image is from McCarter. The micrograph in panel B is of cells grown on surfaces and stained with 0.5% phosphotungstic acid; image is from McCarter LL. "Multiple modes of motility: a second flagellar system in *Escherichia coli*." J Bacteriol. 2005 Feb;187(4):1207–9. PubMed PMID: 15687183; PubMed Central PMCID: PMC545644.

Accessory Motor Parts: Clutches and Brakes

Motility without maneuverability is not a highly effective way to get around, and numerous accessory proteins influence directional and gear changes (Fig. 2(C)). The switch component proteins (FliG, FliM, and FliN) assemble dynamically and their configuration is influenced by the chemotaxis signaling protein CheY, whose phosphorylation status is controlled by the chemosensory system. Binding of CheY~P to FliM and FliN induces cooperative remodeling of the switch complex by inducing dissociation of some FliM/N complexes, and this determines directionality of motor rotation. For many bacteria, this induces reversal of the direction of rotation, although for some organisms, like *Rhodobacter sphaeroides*, CheY~P works like a brake to halt rotation.

Other proteins impact motor function. In *E. coli*, YcgR represents a class of proteins used by many bacteria to control flagellar rotation. These proteins contain a c-di-GMP-binding domain, PilZ. For most bacteria, high concentrations of this second messenger diminishes motility. In the presence of c-di-GMP, YcgR interacts with FliG in the rotor to prevent rotation. Other c-di-GMP-binding proteins like *B. subtilis* MotI and *P. aeruginosa* FlgZ bind to MotA homologs; this interaction disengages or blocks engagement of the torque generator at the rotor. Another motor-binding protein that seems to work via interference to decrease power applied to the rotor is *B. subtilis* EspE, which is a glycosyl transferase that has been shown to interact with FliG. Additionally, extracellular polymers can act to directly encumber flagellar rotation, e.g., cellulose production by *S. enteritidis* jams flagellar action.

Working as gear shifting mechanisms to alter direction of motor rotation, like brakes on the motor to impede rotation, or as clutches to disengage or prevent engagement of the stators at the rotor, these features offer simplicity and speed of action. A molecule interacting with the complex, spinning flagellum can bring its action immediately to a halt or reverse its direction of rotation. These strategies allow bacteria to rapidly and reversibly shift between being motile or sessile. Flagella, which are energetically costly to make and operate, propel bacteria towards optimal environments. Upon reaching an ideal niche, flagellar activity can be efficiently and quickly dampened, held in check by mechanisms such as these. When needed again, motility can be rapidly resumed without the expense of producing new flagella.

Feats of Navigation

Flagellar arrangement on the cell body, motor rotation, and the chemotactic signals that control direction of flagellar rotation produce distinctive modes of locomotion. Most well studied is the free-swimming movement of *E. coli* and *S. enterica*. The swimming pattern of these peritrichously flagellated bacteria, which have ~6 flagella around their rod-shaped cell bodies, is characterized by alternating periods of “runs and tumbles” that are the product of counterclockwise (CCW) or clockwise (CW) motor rotation, respectively. CCW turning motors result in flagellar bundling and smooth propulsion, while a motor that switches to a CW direction will cause the bundle to fly apart and the bacteria will tumble and reorient. Since bacteria are too small to sense spatial changes in concentration, they use a temporal mode of chemical detection. In the absence of sensory input, the swimming trajectories are described as “random walks” that result from alternating periods of smooth runs and tumbles. Chemotaxis biases the movement in a favored direction by controlling the frequency spent in CCW and CW modes of motor rotation, allowing the bacterium to make net progress towards or away from chemical gradients in their environment.

Polarly flagellated bacteria behave somewhat differently. When the motor changes direction, the bacteria reverse direction and back up. However, the reversal of the propeller causes a subsequent buckling deformation of the flexible hook that links the propeller to the rotor. This results in reorientation of the direction of cell movement. This pattern is called a “run-reverse-flick”.

Uniflagellated *Rhodobacter sphaeroides* does not have a bidirectional motor. Its swimming pattern alternates between “runs and stops.” This strategy of using a motor that only turns in one direction achieves much the same consequence as tumbling. Due to conformational changes induced in the flagellar filament, stopping causes cell reorientation.

Swarming Behavior

Swarming is flagellar-assisted movement on surfaces. Like swimming, swarming requires a fluid environment. However, this is movement in a structured environment, and it often results in complex and beautiful pattern formation. Swarming colonies can be smooth films resulting from rapid radially expanding surface colonization, or they have complex architectures with terracing or fractal patterns. Some examples of swarming pattern formation are shown in Fig. 4(A and C); however, the diversity of the swarm architecture is astonishing (e.g., see “Relevant Websites section”). The colony geometries produced by this form of collective behavior is dependent on many conditions, including the type of surface (e.g., agar concentration and type), nutrient composition of the growth medium, temperature and humidity, surfactant production, cell-cell signaling, and features unique to the organism (e.g., cell body shape and flagellation pattern).

The advancing edge of a swarm is a layer of cells that move in packs (Fig. 4(B and D)). A variety of maneuvers can be observed during swarming: Straight movement, stalls which occur at the advancing edge, lateral movement, and reversals. Movement of the swarm often looks like streaming swirls, and the pack moves forward for longer times than single cells. Much of the analysis of bacterial acrobatics on a surface has been done using *E. coli* on 0.45% agar medium; however, there are significant differences between *E. coli* and some of the more robust swimmers such as *P. mirabilis*, *Rhodospirillum centenum*, and *V. parahaemolyticus*. These bacteria swarm proficiently under restrictive conditions (e.g., 1.5% agar medium). During swarming they can differentiate to

Fig. 4 Swarming can be a social activity resulting in complex pattern formation. (B) Zoomed images at the edge of one of the condensed vortices (bright spots in panel A). (D) Zoomed images of swarmer cells at the edge of the swarming colony in panel B. A and B are images from Ingham, C.J., Jacob, E.B., 2008. Swarming and complex pattern formation in *Paenibacillus vortex* studied by imaging and tracking cells. BMC Microbiol. 8, 36. <https://doi.org/10.1186/1471-2180-8-36>. PubMed PMID: 18298829; PubMed Central PMCID: PMC2268691. C and D are fluorescent images of a *V. parahaemolyticus* strain carrying a GFP plasmid.

become very long swarmer cells ($\sim 20\text{--}40\ \mu\text{m}$) with hundreds of peritrichously arranged flagella (Fig. 3(B)); moreover, the robust swimmers demonstrate directed movement (e.g., chemotaxis and phototaxis) on a surface, which *E. coli* does not. Thus, it will be interesting to learn how elongation and hyperflagellation as well as chemotaxis affect swarming behavior.

Reversals on a surface occur when the motor changes rotational direction, and the flagellar filament undergoes polymorphic shape transitions. When this happens for *E. coli*, the cell body can back up through its “tail.” The flagellar bundle, which has pushed the cell body, then becomes a screw that pulls the cell body. Motor reversal can also result in flagella that wrap around the cell: The flagella of polarly flagellated bacteria like *S. putrefaciens* can coil around the cell body and to propel the bacteria backwards in a screw-like fashion. This kind of flagellar wrapping effectively promotes movement through restricted, mucus-filled passageways, e.g., when *Burkholderia* species infect the bean bug and while *Vibrio fischeri* travels to the squid symbiotic organelle. The ability for the organism to dexterously extract itself from a tight spot or dead-end is probably of great advantage in structured environments like the soil, tissue, mucus, or biofilms.

Movement on a surface involves population behavior. Cells tend to move in coordinated packs, e.g., resulting in the striking “bulls-eye” terracing signature of *P. mirabilis* or the beautiful fractal colony patterns captured in the photography of Eshel Ben-Jacob. Since swarming motility is promoted by self-production of wetting agents, population density can be important in establishing the optimal conditions conducive to swarming. Cell-cell communication plays a role during swarming in some bacteria. Quorum sensing and the accumulation of N acyl-homoserine lactone autoinducers induces the production of the surface wetting agent serrawettin by *Serratia liquefaciens* and rhamnolipids by *Burkholderia* and *Pseudomonas* species. Another kind of autoinducer, the S signal produced by *V. parahaemolyticus*, modulates induction of the swarming gene expression program through control of c-di-GMP production. Thus, swarming motility is an important model for social behavior in bacteria.

The Flagellum as a Sensor Signaling Environmental and Lifestyle Switches

Not only is the flagellum a propulsive organelle, but it also acts as a sensor allowing bacteria to discriminate and adapt to their environment, e.g., between life in liquid or on a surface or viscous environment. As previously discussed, one response to mechanical impedance of flagellar rotation involves loading more stators at the rotor to increase the torque for rotation. Although

the molecular mechanism of motor remodeling is unclear, surface sensing may involve detecting the capacity to generate torque and be responsive to load as well as ion availability or ion flux through the stator.

Impedance of flagellar rotation modulates additional cellular activities. Often this involves reprogramming gene expression or activation of enzyme activity. For example, viscous drag on the flagella of *B. subtilis* increases production of DegU~P, a regulator that induces transcription of genes important for biofilm formation, transformation, and persistence. For *Caulobacter crescentus*, inhibition of rotation of its polar flagellum stimulates production of the second messenger c-di-GMP and synthesis of the holdfast polysaccharide adhesion. For *Vibrio parahaemolyticus*, impedance of polar flagellar function – physically by growth on a surface or in high viscosity, genetically by mutation, or by using the sodium channel blocker phenamil to interfere with torque generation by the polar motor – leads to profound differentiation to the swarmer, an elongated, hyperflagellated cell. Differentiation is the result of induction of a program of gene expression called the surface sensing regulon. Containing ~70 genes, the regulon includes genes involved in motility, chemotaxis, c-di-GMP metabolism, cell-cell communication, and virulence. Reducing polar flagellar function of *V. cholerae* increases virulence gene expression. Correlation with pathogenesis is a common theme: Virulence gene expression and, in some cases, antibiotic resistance are co-regulated with swarming in many organisms, including *P. mirabilis*, *P. aeruginosa*, and *S. enterica*. Thus, the flagellum serves as a mechanosensor to inform many other cellular activities, aiding adaptation to viscosity and a surface-adapted lifestyle in the environment and the host.

The Important Roles of Swimming and Swarming

Flagellar propelled motility works robustly under a variety of conditions to get bacteria where they need to go. This can be swimming up a gradient of attractant towards a more favorable environment or away from a toxic chemical. The purple photosynthetic *Rhodospirillum centenum* forms swarm colonies that migrate towards light. The nitrogen-fixing soil bacterium *Azospirillum brasilense* swims to oxygen concentrations that are optimal for energy production. Polar and lateral flagella of the deep-sea bacterium *Photobacterium profundum* work to promote swimming and swarming at high pressure.

Flagella are important for multiple steps in surface colonization and biofilm development on abiotic surfaces and in hosts. Flagella and chemotaxis promote arrival at a surface, and swimming propulsion may overcome some of the physiochemical forces that serve as barriers at interfaces. Studies have shown that flagellar motility is critical for initial stages of biofilm formation and in fact, swimming speed correlates positively with attachment rate to glass. Moreover, the flagellar filament itself may be decorated with molecules that aid adhesion – via charged or glycosylated features of the flagellin subunit itself or by adhesins decorating the membrane sheath of the flagellum. Although swimming into the proximity of a surface plays a critical role in initiation of biofilm formation, flagellar motility also contributes to the timing of development and architecture of the biofilm structure. *Pseudomonas aeruginosa* mutants that do not make flagella or have chemotaxis defects do not form the typical mushroom-shaped biofilms.

Flagellar motility plays key roles in host colonization, and for some bacteria it is required for productive infection. Non-motile or non-chemotactic *H. pylori* and *C. jejuni* are unable to colonize the gastrointestinal epithelium. Swimming motility aids penetration of the host mucosal layer in *V. cholerae* infections. In many bacteria – and not only during swarming as mentioned above – flagellar and virulence gene expression are co-regulated. Flagella and swimming elicit host immune responses; they can activate phagocytosis to allow entry into host cells and play roles in macrophage escape. Swimming *P. aeruginosa* promotes the formation of extracellular traps by neutrophils (NETs). And for some bacteria, the flagellar export apparatus secretes not only flagellar proteins, but also virulence factors, e.g., the phospholipase of *Yersinia enterocolitica* or secreted invasion factors of *C. jejuni*. Motility is also important during infection for dispersion to new sites of infection and for allowing new rounds of infection.

Motility can promote or be the consequence of social interactions among bacteria, fostering cooperative or competing interactions or even division of labor. The cooperative swarming motility of *Paenibacillus vortex* results in complex colony development allowing invasion of toxic environments and sometimes, the transport of helper, non-motile cargo bacteria. Swarming can result in group warfare: The social interactions of swarming colonies of *P. mirabilis* or *P. aeruginosa* result in sharp territorial lines (called Dienes lines) that are the consequence of one group inhibiting growth or killing another group. In addition, rapid movement in a pack can provide some protection from antibiotics.

Motility is critical for establishing many symbiotic relationships. It is essential for the marine luminescent *Vibrio fischeri* to establish its symbiotic relationship with the Hawaiian bobtail squid, in part because motility allows the bacterium to navigate its approach to the light crypt. Furthermore, rotation of the membrane-sheathed flagella of *V. fischeri* produces lipopolysaccharide-rich outer membrane vesicles that elicit host immune responses. Many of the microbes that associate with plant roots in the rhizosphere require flagellar-based motility for establishing their interaction, including *Rhizobium*, *Azospirillum*, and *Pseudomonas* species.

Summary

Thus, the extremely powerful and adaptable mechanisms of flagellar motility allow bacteria to exploit and colonize diverse environments. Fuel source, motor and propeller design, speed, and flexibility are all motility parameters that vary greatly among flagellated bacteria. The motors are often complex and sophisticated machines that can be adjusted under changing demands for increased torque. Some bacteria possess dual flagellar systems for fast swimming and powerful swarming. Others have multiple types of torque generators that differentially engage to accommodate fluctuating conditions such as pH, salt concentration or

second messenger activity. Alternately, other bacteria have a single flagellar system, which is used for swimming and is greatly upregulated to produce more flagella during swarming. Social interactions also factor into modulating bacterial behavior during swarming. Studying the complexity and underlying mechanisms of this robust form of locomotion is crucial for understanding bacterial migration and survival strategies, and may provide insight for promoting or paralyzing bacterial colonization.

Glossary

magic bullet The name given to Paul Ehrlich's Salvarsan, the first specific antibiotic, representing the hope that use of a specific drug to kill the specific bacterial cause of syphilis would control the disease.

morbus gallicus (the French disease) The most common name given to a new disease which appeared in Europe in the late fifteenth century; many physicians and historians identify morbus gallicus as syphilis.

paleopathology The technique of examining ancient skeletal remains to identify the diseases suffered by historical populations.

Treponema pallidum The bacteria that causes syphilis. Other subspecies, all extremely similar to each other, cause endemic syphilis (bejel), yaws, and pinta.

Abbreviation

CDC Centers for Disease Control and Prevention

Defining Statement

Despite centuries of study by historians and scientists, using the latest techniques of molecular biology, details of the origins and spread of syphilis remain unclear. Moreover, despite the existence of decisive treatment, syphilis has not been eradicated and instead thrives wherever social and political conditions allow.

Introduction

The history of syphilis has long been one of the most popular topics in the history of medicine. Despite 500 years of research and debate by historians, physicians, and anthropologists, many questions about the origins of the disease remain unresolved. The evolution of syphilis since the sixteenth century demonstrates remarkable changes in both its medical symptoms and the cultural meanings of those symptoms. The history of efforts to control syphilis reveals the inevitable moral judgments about syphilis and other sexually transmitted infections, the balance between disease control and individual rights, and the limited ability of even powerful medical remedies to control the disease. These lessons take on new relevance as fears of HIV/AIDS motivate efforts to eradicate syphilis.

The Origins of Syphilis

The recorded history of syphilis began in the late fifteenth century with the appearance of a new disease, widely called 'morbus gallicus', the French Disease. The earliest cases were described in 1495 as the mercenary army of French King Charles VIII retreated from its siege of Naples. Victims suffered from fevers, open sores, disfiguring scars, and disabling pains; many were consumed by the disease and met gruesome deaths. As the French army disbanded, infected soldiers carried the disease throughout Europe, to Germany in 1495, and to Holland, England, and Greece by 1496. The voyage of Vasco da Gama took it to India in 1498. By 1505 it had reached Japan. Witnesses described the disease with horror. Joseph Gru'nbeck (1473–1532) left a typical account: 'In recent times I have seen scourges, horrible sicknesses and many infirmities affect mankind from all corners of the earth. Amongst them has crept in, from the western shores of Gaul, a disease which is so cruel, so distressing, so appalling that until now nothing so horrifying, nothing more terrible or disgusting, has even been known on this earth'. This dramatic appearance has puzzled observers for centuries. The 1490s witnessed great transformations in Europe: Columbus encountered the Americas; France invaded Italy; the Spanish government expelled Jews and Moors from Spain; the Pope abolished leper hospitals. Each of these factors might have contributed to the emergence of a new disease. Spanish witnesses traced the disease to Columbus's voyages to

This article is a reprint of D.S. Jones, Syphilis, Historical, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 91–96.

the Americas: they heard from natives that the disease had long been endemic in Hispaniola, and they witnessed unchaste Spaniards acquiring the infection while there. Details of the timing of the early Spanish voyages suggest that syphilis could have been carried back from the New World to Spain in time to appear in Italy by 1495. This would make syphilis the counterpart to the many diseases, notably smallpox, which the Spaniards carried from Europe to America. However, definitive evidence does not exist.

The traditional alternative to this theory asserts that syphilis always existed in Europe and Asia, but was not recognized before the 1490s. Detailed analyses of Egyptian papyri, the Hebrew Bible, Hippocratic writings, and medical texts from India and China contain abundant evidence of the prevalence of sexually transmitted infections. However, these records do not provide clear evidence of the specific presence of syphilis. Ambiguous medieval descriptions of leprosy, which observers believed could be transmitted sexually, have caused particular confusion.

Several novel explanations have been suggested in recent decades. Four distinct diseases – venereal syphilis, endemic syphilis (bejel), yaws, and pinta – are all caused by the same species of bacteria, *Treponema pallidum*. Scientists have long been unable to find histological or immunological differences between the subspecies that cause these different diseases. This suggested that the four diseases might simply be different manifestations of infection with the same microbe, with the results of infection depending on social and environmental conditions. Yaws and endemic syphilis, long present in Europe, transformed into venereal syphilis in the fifteenth century when changes in sanitation, personal hygiene, and sexual behavior produced new conditions favorable for the venereal transmission and manifestations of the disease. A competing theory argued that differences did exist and that venereal syphilis emerged as a result of new and virulent mutations in existing subspecies of *T. pallidum*. This theory has won support from recent genetic analyses. In 1998 scientists sequenced the 1 138 006 bp of the treponema genome. Subtle variation, at only 1000 bp, distinguishes the subspecies that cause venereal syphilis, endemic syphilis, and yaws. When and where did these subspecies emerge? Immunologists looking for the origins of syphilis have sought treponemal antigens in mummies and skeletal remains, finding the oldest in a Pleistocene bear from Indiana. Paleopathological evidence, from thousands of bones from pre-Columbian America, Europe, Africa, and Asia, confirms the presence of treponemal infections in each location. Although interpretation has been controversial, researchers are now confident in their ability to distinguish the bony lesions caused by the different subspecies. Such analyses suggest that yaws has long existed in Africa, Europe, Asia, and America. Syphilis, in contrast, first appeared in the Americas 2000 years ago, returned to Europe with Columbus's crews, thrived in its new environs, and produced the outbreak of morbus gallicus. This story, however, is not fully supported by genetic analyses, which confirm neither the status of the yaws subspecies as the ancestral form nor the status of the syphilis subspecies as a recent arrival. Recognition of the existence of lateral gene transfers between the subspecies further confuses these analyses. As a result, the hopes that state-of-the-art science would finally resolve this historical question remain unfulfilled.

The History of a Disease

The new disease had many dramatic impacts. Observers were horrified by its emergence and manifestations. Everyone blamed someone else. The Italians called it the 'morbus gallicus' or the 'mal francese'. The French named it the 'mal de Naples'. Others labeled it 'scabies hispanicus', the 'American disease', or – in Japan and the East Indies – the 'Portuguese disease'. Some names reflected its manifestations: the 'Great pox', 'fire-piss', 'gangrene grossa', the 'Neapolitan itch', and 'plum-blossom sores'. 'Syphilis' first appeared in the 1530 Latin poem of humanist and physician Girolamo Fracastoro (1483–1553), but this name was not widely used until the eighteenth century.

Early observers traced syphilis to astrological origins, noting the ominous conjunction in 1484 of Mars, Jupiter, and Saturn in Scorpio, the constellation most closely associated with genital affairs. By the 1520s, the disease had been connected to sexual transmission and given a new name: 'lues venerea', the venereal disease. Many people saw the disease as a punishment from God for sexual debauchery (Figure 1). Public bath houses closed, distrust divided friends and lovers, and Platonic love emerged as a vibrant social cult.

Physicians struggled to understand the disease for centuries. Many perceived the varied symptoms, including urethral discharges, penile chancres, and skin rashes as a single phenomena, all caused by a single poison. However, over the eighteenth century, the concept of a single disease became increasingly contested and physicians increasingly argued for the existence of many different 'morbi venerei'. This debate drove English physician John Hunter (1728–93) to his famous 1767 experiment. He reportedly inoculated his own penis with pus from a patient with gonorrhea; when he developed a characteristic syphilitic chancre, he concluded that the existence of a single lues venerea had been proven.

Careful work over the nineteenth century settled the controversy. In 1838, Phillipe Record (1799–1889) reported the results of over 2500 experimental inoculations performed at a Paris hospital. He demonstrated that the primary, secondary, and tertiary stages of syphilis all represented a single disease, distinct from other venereal infections. Rudolf Virchow (1821–1902) and Alfred Fournier (1832–1913) extended this work, describing the characteristic pathological lesions of syphilis and the consequences of congenital infection. In 1879, Albert Neisser (1855–1916) settled lingering doubts by isolating the gonococcus, the causative agent of gonorrhea. The characterization of syphilis, in its modern form, was completed in the early twentieth century. In 1905, protozoologist Fritz Schaudinn (1871–1906) and syphilologist Erich Hoffman (1869–1959) described the slender, spiral bacteria, *Spiriochaeta pallidum*, later renamed *T. pallidum*. In August 1906, Wassermann (1866–1925), working with Neisser and Carl Bruck (1879–1944), developed the Wasserman test, a complement fixation reaction which became the definitive serological test for syphilis. The disease had been defined, the agent identified, and an objective diagnostic test developed.

fessoris.

Figure 1 Illustration from Joseph Grunpeck's 'Tractatus de pestilentiali scorra, sive mala de Franzos' (1496). This image is traditionally interpreted as showing rays of divine wrath striking sinners with syphilitic lesions. It illustrates theological interpretations of the appearance of the new epidemic.

Managing Syphilis

When morbus gallicus first appeared, physicians treated its victims by purging their bodies of its poison. They recommend hot houses and extreme exercise (ball games, running, boar-hunting, or farming) to induce sweating. They practiced blood-letting and prescribed purgatives. Mercury, given topically or orally to induce sweating and salivation, became popular. Its severe side effects – loss of teeth, gum ulcerations, skeletal deterioration, and gastrointestinal problems – matched the severity of the disease. Such punitive treatment seemed appropriate for a disease attributed to venery. However, patients and physicians soon became confused about which symptoms came from the disease, and which from the treatment.

In the 1510s, guaiac, a resin extracted from a West Indian tree, arrived in Europe. Although expensive, and not explained by medical theories, guaiac quickly became popular as rumors credited it with miraculous cures. It satisfied a popular theory that treatments for a disease ought to come from the same place (the Americas) as the disease itself. In addition, its side effects were much less severe than those of mercury. Desperation led physicians to attempt many other treatments: massage, tobacco smoking, abstinence from pork and peas, and decoctions of vulture broth with sarsaparilla. Hospitals and hospices appeared throughout Europe. Most were established as hospitals for the incurable, but as the effects of the Great Pox moderated over the century, they increasingly became places for cure and care. The Catholic Church even developed a special mass, 'Missa contra morbum gallicum'.

Mercury and guaiac dominated syphilis treatment for centuries. Surgeons developed ways to excise or cauterize the sores. Medical entrepreneurs produced and marketed secret remedies. But by the late nineteenth century, some physicians had begun to suspect that their treatments provided no benefit. This suspicion was confirmed by the famous Oslo Study, in which 2000 patients, between 1890 and 1910, received no treatment, and fared just as well (or poorly) as those receiving mercurial ointments and other treatments. The infamous Tuskegee Syphilis Experiment sought to extend the results of this study by describing the 'natural history' of syphilis among African-American men in the rural south. Public Health Service officers deceptively promised treatment, but then provided none, from 1932 until 1972. But in contrast to the Oslo Study, these physicians withheld treatments – including penicillin – which they believed to be effective.

As physicians and scientists struggled to develop effective treatments of syphilis, its prevalence steadily increased. In the nineteenth century, syphilis fueled widespread fear of cultural decay and the breakdown of social values. It was identified as a

family poison which spread from profligate men to their innocent wives and children. Fears of casual transmission – through pens, pencils, drinking fountains, toilet seats, and doorknobs – proliferated. In the United States, immigrants were stigmatized as a source of infection. These fears, which reveal deep cultural anxieties about disease and sexuality, motivated many attempts at social engineering. Shocked to learn that as many as one-third of its troops were infected with syphilis, the British government passed the Contagious Disease Acts of 1864, 1866, and 1869. The laws acknowledged that sexual continence was an unrealistic goal. Syphilis could only be contained by minimizing the consequences of the inevitable transgressions: prostitutes would be inspected and, if infected, detained until cured. These laws produced an outcry from purity reformers, who argued that prostitution needed to be criminalized and repressed, not acknowledged and regulated. The laws were repealed in 1886.

Similar calls for social hygiene dominated syphilis control in the United States from the 1890s through the 1920s. Education and moral encouragement beseeched men to be disciplined and restrained, faithful to their wives and families. During World War I, the US military, which saw syphilis as a substantial threat to its effectiveness, conducted extensive campaigns against the disease. Just as they drained swamps to prevent malaria, public health officials shut down red light districts and detained 20 000 suspected prostitutes. The Training Camp Commission distracted soldiers with organized sports and educated them with unambiguous messages: 'A German bullet is cleaner than a whore'. Faced with the French system of regulated prostitution, the Army refused to distribute condoms. Instead, officials established prophylaxis stations to provide treatment if exposure occurred. They hoped that the painful urethral irrigations would be a disincentive to sex. The Navy contributed to the campaign by removing doorknobs from battleships to prevent transmission of syphilis among sailors. Despite all of this work, syphilis rates remained high.

After the war, interest in venereal disease control diminished. Prudish censorship blocked public education in magazines or on the radio. Surgeon General Thomas Parran (1892–1968) led a campaign to reverse this. He decried the 'conspiracy of silence' that surrounded venereal diseases. He argued that sexual continence remained an impossible ideal and that victims of syphilis were victims of a disease and not criminals. His efforts led to the 1938 National Venereal Disease Control Act, which provided federal funding for diagnosis and treatment. States began requiring premarital serological tests (Figure 2). This new pragmatic attitude dominated efforts during World War II. Moralistic campaigns against venereal diseases did continue (Figure 3). But instead of repressing sexual behavior, officers of the Social Protection Division sought to modify it: instead of providing moral education, they distributed condoms. These efforts substantially reduced the incidence of syphilis among military personnel.

The contrast between the efforts during World War I and World War II illustrates the two extreme options of social management of syphilis. Social hygienists asserted a moral ideal and believed that abstinence was the only way to prevent infection. Pragmatists, in contrast, acknowledged that pre- and extramarital intercourse were inevitable; they sought to prevent infection by encouraging safer sexual practices and by providing unstigmatized treatment.

Figure 2 'Happiness Ahead – for the Healthy but not for the Diseased'. During the 1930s, many states began to require premarital screening for venereal diseases. In this poster from a public health campaign, syphilis was portrayed as poison that would destroy marriages and families.

Figure 3 'V.D.: Worst of the Three'. During World War II, the United States military waged a campaign against syphilis that combined clearly moral messages, as seen in this poster, with condom distribution campaigns. Note that in this image, venereal disease is personified as an evil, dangerous woman, and not as a promiscuous soldier.

The Limits of Biomedicine

While public health officials swung between these two extremes of social management, medical researchers gradually produced powerful methods of medical management. In 1909, Paul Ehrlich (1854–1915) announced that his new drug, Salvarsan, had specific activity against syphilis. It was the first time anyone had found a specific drug that killed a specific microbe. Ehrlich called it a 'magic bullet'. With this drug the promise of modern medicine seemed fulfilled: medical scientists had established the specific cause of syphilis, they had developed a specific diagnostic test, and they had a specific treatment. The control of syphilis seemed at hand. Hopes for easy control went unrealized. Salvarsan was toxic and difficult to administer, with some patients requiring two years of treatment; only 25% of patients received the full series of injections. Hope was restored in 1943 when John F. Mahoney (1889–1957) demonstrated that syphilis could be cured with a single injection of penicillin. The miracle drug had been found. Incidence fell rapidly, from 94 957 cases in 1946 to only 6392 cases 10 years later. Syphilis seemed vanquished.

But again, syphilis defied expectations. Despite the power of penicillin, syphilis began a slow recovery during the 1960s. Many factors have been implicated: the promiscuity of the sexual revolution, the availability of oral contraceptives, and decreased funding for education, case tracing, and other disease control programs. Some physicians even refused to prescribe penicillin, fearing that easy treatment only encouraged illicit sexual activity. Whatever the cause, syphilis rates began to rebound. Rising and falling in 10-year cycles, with each peak higher than the last, by 1990 the incidence of syphilis had risen to 50 578, the highest number of cases seen since 1948, with most of the burden falling on impoverished, minority populations. How could syphilis continue to spread despite the existence of penicillin, an affordable and decisive treatment? 'Magic bullets', even those as powerful as penicillin, are never panaceas. The history of syphilis shows the range of scientific, social, political, and cultural factors which contribute to the prevalence of the disease. A single intervention cannot treat the many different problems which become embodied as syphilis. Successful management requires concerted efforts against all of the causes of the disease.

Interest in the history of syphilis took on new urgency in the 1980s with the appearance of HIV and AIDS. Syphilis became both a significant facilitator of the transmission of HIV and a dangerous infection in people with AIDS. In addition, public health officials and policy makers turned to the history of syphilis to guide their efforts against HIV. Many lessons were suggested. Just as penicillin had not solved syphilis, effective treatments for HIV would not end the epidemic. Educational programs, whether advocating abstinence or safe sex, would not cause people to avoid high risk sexual behaviors. Compulsory measures, whether quarantine or serological screening, would bring few results, at high costs to civil liberties. Fear, blame, and stigmatization would shape the development of public health policy.

This new urgency, combined with growing awareness of the risks of sex, fueled more aggressive public health efforts that, combined with periodic ebbing of the prevalence of disease, reversed the slow rise of syphilis. By 2000 the Centers for Disease Control and Prevention (CDC) reported only 5979 new cases, the lowest number reported since it began keeping data in 1941. This reversal triggered optimism that syphilis could be contained. The CDC launched a National Plan to Eliminate Syphilis, which initially made substantial progress. Cases fell most dramatically among African Americans, women, and newborns; the black: white disparity in incidence dropped from 28.6:1 to 5.6:1. However, despite this progress, the absolute number of cases has increased since 2000, reaching 8724 by 2005. Most of the growth has been among men, but rates have also begun to increase among women. Proponents of elimination have known that the most important barriers to eradication would not be scientific, but rather the considerable social and economic obstacles that exist. Syphilis continues to be seen as a moral problem, reducing the willingness of victims to seek treatment. It flourishes in communities which lack basic financial and social resources, which perceive more serious threats from education, unemployment, crime, and other health issues. The shadow of the Tuskegee study has also left many afflicted communities suspicious of public health campaigns. The situation is much worse in developing countries, with roughly 12 000 000 cases worldwide each year. This represents an enormous toll of preventable morbidity, especially in light of the synergy of syphilis and HIV.

The history of syphilis, therefore, demonstrates many important characteristics of diseases. Syphilis is not simply a biological phenomena. Instead, its incidence reflects political and economic structures and cultural beliefs and practices. Its manifestations and meanings change over time, shaping efforts to control the disease. Isolated medical remedies, even those as powerful as penicillin, cannot be the only solution. Successful control requires comprehensive programs, which acknowledge the cultural and social dynamics of syphilis.

Glossary

Archaea A domain of prokaryotic cells with no nucleus, that are distinct from bacteria in that they have evolutionarily unique ribosomal RNA, cell membrane and metabolic components; 'archaeal': pertaining to the archaea.

Aseptic free of microorganisms; not-infected; not-contaminated.

Astrobiology Also called 'exobiology' and 'space biology'; a branch of biology that searches for living organisms (in microbial form) on other planets and their satellites.

Bacteriophage Viruses that infect bacterial cells in order to reproduce and propagate; named so because certain of them, when plated on a lawn of bacteria, form plaques or holes in the lawn, hence 'bacterio-phage' which means 'bacteria eater'.

Bioinformatics A field that combines biology, computer science, and statistics to analyze the large datasets that result from studying an entire genome's worth of information, including the genes that are expressed and the proteins that result from the expression.

Bioterror Terrorism or threats that employ the use of biological agents, organisms or products that they synthesize, to harm individuals or a community.

Competent cells Cells that are able to take up exogenously supplied DNA.

Genomic Having to do with the complete DNA composition of an organism; usually referring to the complete sequence of the chromosomal DNA of an organism.

Immunochemistry The use of antibodies to detect the presence of another molecule in a sample, usually a protein or glycoprotein.

Nanotechnology A field of science that seeks to understand and build structures using atoms and molecules as components. Bacteria are natural nanotechnologists and provide model products.

Polymerase chain reaction An in vitro reaction that uses DNA polymerase from thermophilic bacteria to amplify, by repeated cycles, a specific sequence of DNA, targeted by special primers.

Restriction endonuclease Any of a group of bacterial enzymes that may be used to cleave DNA into discrete fragments; usually via recognition of palindromic sequences.

Transformation The process by which the genetic composition of a cell is enhanced by DNA that has entered the cell and has been expressed.

Winogradsky column An in vitro rendition of an ecosystem containing (usually) a source of water, mud/soil, organic carbon (e.g., newspapers), inorganic sulfur compounds, or other source of electrons – that, over time, will become enriched for self-sustaining, interdependent microbial communities and from which bacterial species can be tracked and isolated.

Defining Statement

This chapter provides a description of the diverse roles, audiences, resources and techniques utilized in the area of microbiology education. This includes the impact and importance of different teaching methods, listings of professional societies and their contributions, as well as a limited inventory of websites that represent online resources.

Introduction

There are multiple resources that support faculty and instructors that are involved with microbiology education and teaching. Some of these resources include peers and colleagues, professional organizations, textbook and publishing companies, and other online resources. This article will describe some of these materials. The spectrum of resources for the teaching of microbiology is appreciated by understanding the context in which microbiology is taught: microbiology is not a stand-alone disciplinary subject. Rather, it is often taught within a wider context that may include general biology, cellular biology, molecular biology, biochemistry, immunology, environmental sciences, or astrobiology.

Sources of Material

Textbook Publishers

Textbook publishers provide new, updated editions of microbiology textbooks every few years. With these textbooks there is a wealth of supplementary material for both the student and the educator. Publishing companies have created complementary online learning platforms. Within these platforms, students can access electronic versions of their textbooks (i.e. e-books), which are easily accessible using a variety of electronic devices (i.e. smartphones, tablets and laptops). These online learning platforms may also provide online quizzes and other review questions, short videos and animations to explain concepts, as well as links to other websites and resources. For those faculty and instructors that are teaching microbiology, publishers provide a variety of 'instructor resources'. These resources typically include electronic files of all textbook figures, images and tables, electronic files of suggested power-point slides that can be modified and incorporated into lectures, as well as test-banks. Most test-banks are often only filled with multiple choice questions, but some test-banks will also include extended-response questions. The most effective test-banks include Bloom's taxonomy classifications of test-questions. All of these instructor resources are typically only accessible by instructors with approved accounts with logins and passwords. Account approval usually follows once the faculty member has committed to adopting a particular textbook for use by the students in their microbiology course. Instructors also have access to electronic versions of the textbook content, videos and animations, as well as links to other online resources and websites. Some faculty and instructors may select a textbook for use by the students in their courses solely for the content in the textbook, while other faculty and instructors may select a textbook based on the combination of textbook content and supplementary resources available for both the student and educator. As well, some publishers will provide microbiology textbooks at varying levels (i.e. for courses for introductory lower-level undergraduate students versus advanced upper-level undergraduates) and for various specialized audiences (i.e. general biology undergraduate students, microbiology major's undergraduate students or for students in health-related programs such as nursing, physician's assistant or medical doctorate). In addition, some textbook publishing companies will also publish a hands-on laboratory manual to complement the microbiology textbook.

Professional Societies

The leading professional society for microbiology content in the United States of America is the American Society for Microbiology (ASM). In a similar way, the Canadian Society for Microbiologists (CSM), the European Society in Clinical Microbiology and Infectious Diseases (ESCMID) and the Australian Society for Microbiology (ASM) provide excellent resources for general microbiology content. But more importantly, these societies provide microbiology information relevant to these countries and regions. For example, country-specific outbreaks and policies could be gathered from these resources. Even more importantly, the names and contact information of country and region specific experts in microbiology can be obtained from these resources. While these general societies all serve as resources for microbiology information, several education-specific societies serve as the ultimate microbiology resources for those involved with microbiology education and teaching. Here again, the American Society for

Microbiology is the leading resource in this area with their annual Conference for Undergraduate Educators (ASMCUE). This conference provides an excellent opportunity for those teaching microbiology to exchange ideas related to teaching undergraduate students, creating assessments and how to actively engage students in the microbiology classroom and laboratories. This conference also provides an opportunity for networking, collaboration and, in general, promotes collegiality. Other organizations, such as Society for the Advancement of Biology Education Research (SABER), the National Association of Biology Teachers (NABT) and the National Science Teachers Association (NSTA) serve a broader membership, but are also useful resources for those involved in microbiology education.

Beyond general microbiology and microbiology education, other professional organizations also serve as resources. Some of these US-based organizations include: the Society for Industrial Microbiology and Biotechnology (SIMB), and the American Biological Safety Association (ABSA).

International-based organizations include: the Microbiology Society, the Society for Applied Microbiology (SFAM) and the Microbiology in Schools Advisory Committee (MISAC), which is a consortium that includes the British Mycological Society, consortium of Local Education Authorities for the Provision of Science Equipment (CLEAPSS), National Centre for Biotechnology Education (NCBE), the The Quekett Microscopical Club (QUEKETT), Society for Applied Microbiology (SFAM), Society of Biology and Scottish Schools Equipment Research Centre (SSERC). All of these websites serve as extensive resources for microbiology education at all levels. All society names and acronyms were up-to-date at the writing of this edition.

Individual Educators

Microbiology educators can be as generous as they are creative – most of them freely share their resources with colleagues and those who seek their advice. Such individuals can be found at a variety of institutions. Sometimes, the materials to be shared are available on the individual faculty members' institutional website. More importantly, a faculty members contact information can be found on their institutional website. This information can be used to request materials or to communicate requests for the use of their materials. When using others resources, be sure to cite the original author and give them credit. A few have published their lessons in publications supported by professional societies.

Other Groups, Organizations and Online Resources

Multiple online resources provide ample current and up-to-date material for those teaching microbiology.

1. The *American Association for the Advancement of Science* (AAAS) is committed to the advancement of science for all individuals. Part of their mission is to promote science education and foster innovative teaching of all disciplines of science at all levels, including microbiology instruction.
2. *BioQuest* was founded in the mid-1980s. With a '3P's' approach (problem posing, problem solving, and peer persuasion), it maintains a library of learning modules, tools, databases, curricular activities, and simulations. In particular, the part of their curriculum that focuses on microbiology is called *Microbes Count!* BioQuest also sponsors an annual summer workshop.
3. The *Centers for Disease Control and Prevention* (CDC) is the leading organization in the United States for the control and prevention of numerous bacterial and viral agents. The local and regional information that is provided is useful for understanding transmission patterns, conducting outbreak investigations and preventing future cases of illnesses. Information is available in-text, as images, figures and charts, as well as hand-outs, all of which provide excellent resources for both faculty and students in microbiology courses.
4. The *Howard Hughes Medical Institute* (HHMI) sponsors a competition to award university faculty grants under the 'HHMI University Professorship' program in an effort to highlight and promote effective and creative teaching initiatives at institutions that are often better known for their research. In each cohort of these professor awards, there are numerous microbiologists who have contributed new ideas in the area of teaching microbiology and biology in general. These microbiologists have formed an informal network and support the training of graduate students and postdoctoral fellows who are interested in career trajectories that combine teaching and research in a more integrated manner.
5. *MicrobeWiki* is useful resource on the biology of microorganisms. This resource is a collaborative project with articles and entries authored by multiple users. It provides relevant information on the taxonomic classification of select microorganisms, as well as the genomics, cell biology, metabolism and ecological information of the microorganism in question. The content on this page directly relates to the content covered in an undergraduate microbiology course, which makes it a relevant resource for both faculty and students.
6. The *National Science Foundation's* (NSF) mission is to support the advancement of all fields of science, technology, engineering and mathematics (STEM). By supporting scientists and educators, including microbiologists, NSF aims to encourage scientific inquiry and discovery.
7. The *NIH Human Microbiome Project* website provides current information on the microbiome project. This content can be integrated into microbiology courses when discussing the interaction of microbes with humans, when discussing biotechnology, as well as microbial genomics, applied microbiology and, of course, human health and disease.
8. *Project Kaleidoscope* (PKAL) was founded in the late 1980s with a long-term mission of supporting and advocating for strong Science, Technology, Engineering, and Mathematics (STEM) curricula for undergraduate institutions. Since then, there have been strong initiatives to invigorate K-12 programs involving teacher training and a connection to national and state education

standards in science and mathematics. PKAL has resources such as devoted training institutions, designing facilities, as well as a curriculum design for introducing microbiology as part of a robust elementary and secondary science program. science, technology, engineering and mathematics (STEM).

9. *Waksman Foundation for Microbiology* was founded in 1953 by Nobel Laureate Selman Waksman, who was recognized for his discovery of the antibiotic streptomycin. The Foundation has supported many initiatives in microbiology education and research. It has a library of educational resources and activities. At the writing of this edition, it was unclear whether or not the foundation remains active.
10. The *Wellcome Trust* is an international organization that promotes the advancement of science, research and knowledge. The efforts of this organization aim to improve the health of individuals through the sponsorship and funding of a variety of projects. Some of these projects have involved the development of vaccines against bacterial or viral infectious disease agents.
11. *Woods Hole* (Massachusetts) Marine Biological Laboratory's summer course in Microbial Diversity is an unparalleled resource that has trained several generations of microbiologists in the ecological, metabolic, physiological, and, more recently, genomic diversity represented by bacterial and archaeal species.
12. The *World Health Organization* (WHO) is the global leader dedicated to the health and well-being of all global citizens. Much of the work by the WHO has focused on reducing or eliminating global cases of select infectious disease agents, such as Malaria, Polio, HIV and Smallpox. Based on this, the WHO website provides excellent resources on numerous microbial infectious diseases agents. These resources include information on transmission, spread, growth control, risk reduction, immunization and preventative measures of bacterial, viral and parasitic microorganisms. Such content is integral to microbiology instruction, especially those courses directed towards students in pre-medical sciences or allied health programs.

Diverse Audiences

The diverse audiences of microbiology education predominantly include undergraduate students and students in professional-degree programs. Microbiology education is also delivered at community colleges and in the K-12 curriculum.

Institutions and Curricula

1. *K-12*: The concepts of microbiology are introduced into the K-12 curriculum through topics in general science, personal hygiene, recycling and evolution, to name a few. Microbiology educators have provided resources for K-12 teachers in several ways: laboratory manuals with hands-on activities directed toward middle school science teachers and educational workshops at professional meetings such as the ones sponsored by ASM. In turn, K-12 educators have shared their expertise in assessment and outcome measurement with their counterparts in higher education.
2. *Community Colleges*: Microbiology courses are available to students who are preparing for a transition from secondary school to a four-year college or university. These institutions often provide evening and weekend courses with lecture and laboratory courses are often offered back-to-back in one 4–5-h evening session per week. The greater availability of evening and weekend courses at community colleges allows students to enroll in part-time studies. This is an ideal option for students who have jobs during weekdays and for students wanting to transition or enhance their training in the allied health professions.
3. *Primarily Undergraduate Institutions* (PUIs): Smaller universities (also referred to as Liberal Arts Colleges) will predominantly only offer undergraduate degree courses and programs. Within these institutions, the biology departments will typically have 6–12 faculty members. At least one of these faculty members will have the primary responsibility of teaching microbiology. The microbiology courses offered at these institutions might include introductory microbiology, microbiology for majors and microbiology for pre-health professionals. These courses are often accompanied by hands-on laboratory sessions. These institutions are often committed to offer laboratory sessions, which is especially important in microbiology education. The hands-on microbiology laboratory component is often the most valued by graduate and professional students. The students enrolled within these courses are typically majoring in biology or biochemistry.
4. *Universities*: At larger institutions with undergraduate, graduate and professional-degree programs, microbiology courses can be found in numerous different departments and programs (e.g., biology, cellular biology, molecular biology, biochemistry, immunology or biotechnology departments, as well as environmental science departments and agriculture/agronomy departments). In addition, the study of genomics has placed the study of microbes at the forefront of the evolutionary context of genes and their products. Hence, microbiology courses and the professors who teach them can also be members of departments such as evolutionary biology, geology, astrobiology, nanotechnology, and industrial microbiology.
At all of these undergraduate institutions, microbiology coursework may be required for a variety of majors, including biology, microbiology, biochemistry, cellular biology, molecular biology, biotechnology, public health and other science/engineering majors and non-majors, and for students preparing for professional training in medical and allied health fields.
5. *Professional schools*: Clinical microbiology, medical technology programs, medical, dental, and veterinary schools all include microbiology courses in the core curriculum. Microbes in the biotechnology industry have now found their way into some business schools that offer joint business and biotechnology degrees. While law schools do not have any formal science coursework, high value is placed on lawyers who have training in the sciences, especially in the area where biotechnology, intellectual property, and patents involve genetically modified organisms.

Categories of Resources

Pedagogy

1. *Lectures*: Microbiology courses are predominantly delivered in lecture format. At larger institutions, the lectures are often delivered in a large auditorium space compared to the smaller classrooms of smaller, primarily undergraduate, institutions. Within these lectures, faculty and instructors aim to utilize creative methods of content delivery to better engage students.
2. *Active Learning*: Creative formats of content delivery can involve asking the students to engage in short discussions with their peers on content-related questions or students may be asked to use an electronic response system (also referred to as clickers) to submit their responses to multiple-choice type questions. These active learning techniques were first pioneered in the undergraduate physics curriculum and have expanded across multiple disciplines of science, including microbiology instruction.
3. *Problem-Based Learning and the Flipped Classroom*: Collaborative exercises, cooperative learning, and case studies can place learning more actively in the students' arena. Some of these activities take place within a scheduled class period. Other activities require students to meet and complete course-work outside of the class time. This method of instruction is also referred to as a 'flipped classroom'. Microbiology is well suited for these exercises since case studies that relate to real-world experiences are available in abundance in everyday news stories, which should be of interest to students. Another useful online resource for case-studies is the 'National Centre for Case Study Teaching in Science' supported by the National Science Foundation.
4. *Inquiry Based Learning*: This learning format aims to more actively engage students by posing questions to students that they are instructed to research and solve instead of just delivering content. As students conduct their research to formulate a response, they will engage in collaborative exchange, may pose their own questions and challenge current dogma.
5. *Videos and animations*: Numerous short videos and animations are made available to those teaching microbiology through their chosen textbook publishers' website (see section on 'Sources of Material – Textbook Publishers'). Another resource for content-related videos and animations includes the iBiology website. In recent years, Ted Talks have proven to be a very useful resource on real-world microbiology content. As well, an archived library of images is available through ASM's MicrobeLibrary. In addition, an endless supply of short videos and clips are available on Youtube. All of these resources can be used to supplement lecture content to enhance student engagement and learning.
6. *Laboratories and Investigative Learning*: Hands-on laboratory sessions are instrumental to the instruction of microbiology content. In these sessions, students learn fundamental techniques in aseptic transfer, growth of microorganisms, enumeration of colonies, unknown identification, enrichment for environmental microbes (and Winogradsky columns), isolation and characterization of bacteriophage, as well as molecular techniques including polymerase chain reaction (PCR), cloning, transformation of competent cells, and restriction endonuclease analysis. Other activities might include immunohistochemistry techniques. Published microbiology laboratory manuals are an excellent resource for routine protocols and procedures that are regularly used in microbiology laboratory activities. Some advantages of utilizing published manuals include detailed descriptions of standard protocols, high-quality photographic images, lab questions for students to assess and review their understanding, and accompanying online resources. A significant advantage to using a published microbiology laboratory manual is the fact that most of these manuals also include a complementary preparatory manual. Preparatory manuals are a vital resource for microbiology laboratory sessions as there are numerous different microorganisms to grow and prepare for each laboratory session. Many of these microorganisms require their own distinct growth medium and conditions. Organizing all of this information in a complementary preparatory manual allows microbiology faculty to easily instruct others (i.e. lab technicians, lab assistants or teaching assistants) on how to prepare for an upcoming microbiology laboratory session. Many microbiology faculty may also develop projects in their laboratory courses that are open-ended investigations, which can span the entire semester. Students are motivated by being actively involved in the study-design, preparation, execution, analysis, and reporting of the experiments. Such projects can be used as a tool to recruit and pre-select students to conduct research with the microbiology faculty member.
7. *Safety*: The microbiology laboratory is the place to teach safety in several ways: working with potential pathogens can provide a context for students to be attentive, keep careful records, perform risk assessment, and practice important containment and disposal techniques. Alternatively, safety can be integrated into the microbiology laboratory session with laboratory exercises designed to emulate water quality, food safety, or other measures that are imperative to public health and safety.
8. *Online courses*: Some microbiology courses may be offered as online courses through the same institution and faculty member that teaches the in-person / in-lecture course. Often the advantage of the online course is that it can be offered in the summer when students may not be on campus. As well, online courses can attract students from other institutions, allow students to improve their grade or prepare for the in-semester course. Online courses are also valuable for those working in the allied health professions that are contemplating returning to school to improve their skills. Websites of individual institutions should be consulted for specific courses. The challenge with online microbiology courses is the administration of hands-on laboratory sessions. As a result, some online courses might only be lecture-only courses. In addition to institution-specific online courses, microbiology courses can also be offered as massive open online courses (MOOC). Leading platforms that may offer microbiology MOOCs include: Coursera, edX, MIT Open Course Ware, Udacity and Khan Academy, as only a few examples of the pioneers in massive open online education.

Assessment and Evaluation

1. *Evaluating Student Learning*: Content-based questions are one certain way to assess student-learning. These questions are often administered as mid-term examinations and final-term examinations. Intermittent quizzes, however, can also be included as a way for both students and faculty to assess learning and misconceptions of microbiology content throughout the semester. Student-learning can also be measured by the student's ability to apply, integrate, and synthesize content through course projects, reports, research papers, presentations or through the design of an experiment.
2. *Surveys*: Surveys have been developed by educators in an effort to determine whether a course has achieved its student learning objectives in communicating content, meeting goals, piquing student interest, teaching skills and motivating students to engage in further study. Some instructors may choose to use pre-tests and post-tests of student knowledge to evaluate student gains in knowledge. Interim assessments or mid-course evaluations can also be utilized so that students and faculty can implement mid-course adjustments toward their learning and teaching goals. Microbiology course assessment usually includes probing whether the students have gained an appreciation and understanding of historic contributions of microbiologists as well as the impact of microbes on human history, bacterial physiology and genetics, diversity and evolution, microbial ecology, and the impact of microbes in the composition of the planet. Medically oriented microbiology courses include aspects of microbial pathogenesis, host-pathogen interactions and coevolution, innate and adaptive immunity, as well as growth control and prevention. Environmental and industrial microbiology courses emphasize the learning and retention of processes and application.
3. *Evaluating Faculty Teaching*: These tools allow for the determination of whether the goals articulated and set by the microbiology faculty or instructor have been achieved. Achievement can be measured objectively in a survey format or subjectively in a narrative format. The former allows for statistical analysis via comparative responses to a graded numerical scale. The latter provides important critiques and testimonials that are equally useful.

Scholarship of Teaching and Learning

The scholarship of teaching and learning (SoTL) includes microbiology teaching, but also encompasses an area of professional development and academic contribution for microbiology faculty and instructors. SoTL emphasizes an understanding of the different modalities of student learning with the utilization of comparably varied techniques in teaching. The latter might include diverse methods of assessment, analysis of knowledge acquisition, retention and application of content and integration of new knowledge with prior knowledge. There are numerous SoTL scholars in microbiology, some of whom have been fellows in the Carnegie Academy for the Scholarship of Teaching and Learning. Microbiology faculty engaged in SoTL have graduate training in microbiology and are regularly involved in microbiology education. As a result, some of these individuals will choose to conduct hypothesis-based research on student learning outcomes in the microbiology classroom and laboratory. Some may be involved with SoTL as their main form of scholarship and professional development, while others may engage in SoTL in addition to hypothesis-driven bench research. In both cases, these scholarship and research activities are recognized as hypothesis-based research, evaluation of prior studies in the primary literature, study designs, research execution, data collection and analysis, as well as communication at conferences and in peer-reviewed journals.

Journals

In microbiology, the *Journal of Microbiology and Biology Education* (JMBE) is the leading peer-reviewed publication that publishes original contributions of microbiology faculty conducting research in the area of microbiology education, teaching and learning. Other journals might also contain publications in related topics. Some of these journals include: *Journal of Biology Education*, *Cell Biology Education-Life Sciences Education*, *Journal of Biochemistry and Molecular Biology Education*, and *Journal of Chemical Education*. The latter provide pertinent articles on information related to some techniques that may be practiced in the microbiology laboratory. Each of these journals is supported by the corresponding American professional society. On occasion, the journals *Nature*, *Cell* and *Science* will publish highly relevant articles on science education, pedagogy and teaching at institutions of higher education.

Conferences

The American Society for Microbiology Conference for Undergraduate Educators (ASMCUE) is an annual conference specifically targeted to those involved in undergraduate teaching and education in microbiology. This conference is an excellent resource for understanding and applying new and innovative teaching techniques, for showcasing faculty scholarship and research in teaching and learning, and for networking and exchanging ideas with peers that are equally focused and dedicated to student learning. The value of ASMCUE was recognized by ASM's Education Board (which organizes ASMCUE), which made a strategic planning decision to expand its breadth to include all biology educators. The ASM also sponsors the Biology Scholars programs, which are aimed at advancing scholarly activities in microbiology education. The Society for the Advancement of Biology Education Research (SABER) is another excellent resource for those conducting research on enhancing biology education within undergraduate courses. The Lilly series of conferences on College and University Teaching and Learning also provide useful insight in the scholarship of

evidence-based teaching and learning amongst undergraduate students. The National Academy of Sciences also sponsors an annual summer workshop on undergraduate education in biology. Other professional societies might also sponsor workshops for educators within the purview of their more general professional meeting.

Professional Networks

Conferences and meetings provide a natural outgrowth of networking, as well other group formats can provide support for those teaching in microbiology and related areas. ASM, for instance, also supports a number of regional branch groups and meetings. There are seven distinct regions which include multiple sub-branches. An example of an ASM branch from each of the seven regions include: Eastern New York, Eastern Pennsylvania, Ohio, Southeastern, North Central, Rocky Mountain and Intermountain. Each branch typically hosts their own regional meeting with microbiology faculty from surrounding schools. Often these meetings include a keynote speaker, student poster presentations and a business meeting. These meetings allow attendees to meet local microbiologists, stay current with topics important for lectures, discussions, and laboratory activities. This support of local and regional networks allows faculty to more easily form collaborations in the scholarship of teaching, meet more frequently and discuss region specific student-populations. In addition to annual regional meetings, branch groups often maintain a website, which allows members to quickly extract the contact information of other local microbiologists. Microbiology faculty can also build and extend their professional networks by maintaining active accounts on Research Gate and LinkedIn.

Awards and Recognition

Many colleges and universities recognize teaching excellence among their faculty; such award conferments are posted on the institutional websites. In many cases, the laureates are microbiologists. Wider recognition of excellence in the teaching of microbiology is afforded at several levels. The Society for Industrial Microbiology annually gives the Waksman Outstanding Teaching Award, naming a recipient who 'shall have been an active full time professor at a recognized institution of higher education for a minimum of 10 years or has attained emeritus status. He/she shall have an active involvement in research in his/her teaching field while carrying a teaching load, and involvement in or contributing to research that leads to advances in his/her career of industrial or applied microbiology or biotechnology'. The ASM Graduate Microbiology Teaching Award honors the 'exemplary teaching and recognizes an individual for distinguished teaching of microbiology and mentoring of students at the graduate and postgraduate levels (e.g., graduate school, medical school, or other health professional schools) and for encouraging students to subsequent achievement'. In addition, since 1968, ASM has recognized an undergraduate educator with the Carski Foundation Distinguished Undergraduate Teaching Award for 'outstanding teaching of microbiology to undergraduate students and for encouraging them to subsequent achievement'.

Conclusion

In summary, the field of microbiology is as diverse and interesting as are the students and faculty who explore the discipline. Emerging areas of inquiry that highlight the interaction of microbes with other organisms, such as their commensal hosts, and the impact of global climate change on surges of infectious agents have grasped the attention of microbiologists. Educators have the privilege and challenge to provide a historical backdrop of microbiology (which paved the way for cellular biology, molecular biology, biochemistry and genetics), important general principles of biology illuminated by bacterial model systems, distinctive perspectives such as biofilms and consortia as well as headline-snaring topics like mysterious viruses, drug-resistance bacterial infections (i.e. superbugs), bioremediation and even bioterrorism. Just as new techniques and resources propel investigators to the frontiers of microbiology research, new methods and strategies in science education and teaching motivate microbiology educators to engage students in active learning and inquisitive discoveries.

“So many of the things I’ve predicted were technologies that were just sitting right in front of us”.
Joshua Lederberg

Introduction

Two Elsevier encyclopedia books formed the root of the Medical Microbiology subject: (1) *Encyclopedia of Microbiology*, a “bible” recognized nationally and internationally in the field for decades, was firstly edited by Joshua Lederberg and subsequently by Moselio Schaechter (Lederberg, 1992, Lederberg et al., 2000, Schaechter, 2009), and (2) *Encyclopedia of Virology*, on the other side, was firstly edited by Robert Webster and Allan Granoff and subsequently by Brian Mahy and Mac van Regenmortel (Granoff and Webster, 1999, Mahy and Van Regenmortel, 2008, Webster and Granoff, 1994). Medical microbiology is the branch of microbiology devoted to the study of the physiological and pathogenic processes that underlie microbial infections in human and animal hosts. Medical microbiology covers not only basic components on the biology of pathogens in the context of pathogenicity, but clinical components in the context of epidemiology, diagnosis and treatment as well. The roots of medical microbiology trace back to 1676 when Anton van Leeuwenhoek first observed bacteria and protozoa using a single-lens microscope of his own design. However, it was not until the late 1800s that the work of Pasteur, Koch, and others ushered in the modern era of germ theory as well as the use of isolation techniques on artificial growth media (Maccallum and Hastings, 1899). Since then, the capabilities of modern medical microbiology have expanded and improved rapidly, thanks to technological revolutions in microbiology, immunology, chemistry, physics and molecular biology (Persing et al., 2016, Tang and Stratton, 2013).

During the past decades, technical advances in the field of medical microbiology have made constant and enormous progress in various areas, including etiology, pathogenesis, epidemiology, diagnosis and treatment (Tang et al., 2014, Persing et al., 2016). A major milestone in medical microbiology was the Gram stain. In 1884, Hans Christian Gram developed the method of staining bacteria, to make them more visible and differentiable under a microscope (Gram, 1884). Robert Koch’s work led to discovery or development of bacterial culture by using potato slices, agar (with the help of Walther and Angelina Hesse) and petri dish (developed by Richard Petri) for growth and isolation of microorganisms. In the 1980s and 1990s, immunoassays came into wider usage in both medical microbiology research and practice with the development of radioimmunoassay and immunofluorescence, and then enzyme immunoassay (EIA) and immunoblotting. Application of monoclonal antibodies and antigen-recognizing probes, such as peptides, has significantly increased the sensitivity and specificity of antigen detection and characterization. DNA sequencing, a method developed by Walter Gilbert and Frederick Sanger in 1977 (Sanger et al., 1977, Maxam and Gilbert, 1977), caused a rapid change in the development of vaccines, medical treatments, and diagnostic methods. Subsequently in 1995, a team at the Institute for Genomic Research sequenced the first bacterial genome; *Haemophilus influenzae* (Fleischmann et al., 1995).

Probably the greatest advance in the field of diagnostic microbiology has been in the area of nucleic acid detection and characterization. The polymerase chain reaction (PCR) invented by Kary Mullis (Mullis and Faloona, 1987, Saiki et al., 1985) and other more recently-developed amplification techniques have simplified and accelerated the in vitro process of nucleic acid amplification. Rapid techniques of nucleic acid amplification and characterization, along with the increased use of automation and user-friendly software, have significantly broadened microbiologists’ research and development arsenal. New real-time PCR, multiplex PCR, and microarray techniques provide relevant and accurate microbial quantification and identification, which play important roles in the selection and monitoring of antimicrobial therapy (Tang and Stratton, 2013, Persing et al., 2016). Since 1995, the whole genomes of an increasing number of bacterial species has been described and this has opened up the so-called “omics” technologies (Lederberg and McCray, 2001), which cover the areas of genomics, transcriptomics, proteomics and metabolomics (Kiechle and Holland-Staley, 2003) (Table 1). These panomic techniques, along with microarray and sequencing, can be used to generate microbial pathogen profiling for management and surveillance (Sintchenko et al., 2007, Goh and Knight, 2017) that play roles in classification, metabolism, pathogenesis, genetics, host responses, epidemiology, diagnosis and treatment of medical microbiology (Fig. 1).

Microbial genomics dissect and analyze the function and structure of genomes, the complete set of nucleic acids within a single microorganism. Ramet et al. devised a functional genomic analysis of phagocytosis and identification of a *Drosophila* receptor for *E. coli* and demonstrated that peptidoglycan recognition protein LC was an essential component for recognition and signaling of Gram-negative bacteria (Ramet et al., 2002). Bioinformatic analyses of bacterial 16S rRNA gene data revealed *Schistosoma mansoni* infection is associated with quantitative and qualitative modifications of the mammalian intestinal microbiota (Jenkins et al., 2018).

[☆]Change History: April 2019. Yi-Wei Tang update the text throughout the article.

This article is an update of Yi-Wei Tang, Technology Advances in Medical Microbiology, *Reference Module in Biomedical Sciences*, Elsevier, 2014.

Table 1 Panomic techniques in medical microbiology

Panomic technique	Question addressed	Target molecule	Large-scale data	Main method(s)
Genomics	What can happen? (potential)	DNA	DNA sequences	DNA sequencing
Transcriptomics	What is the plan? (strategy)	RNA	RNA transcript profile	RNA sequencing; real-time RT-PCR
Proteomics	What is happening? (process)	Protein	Protein profiling	MALDI-TOF MS
Metabolomics	What happened? (products)	Metabolites	Metabolite profiling	GC-MS

Abbreviations: MALDI-TOF MS, matrix-assisted laser desorption/ionization time of flight mass spectroscopy; RT, reverse transcriptase; GC-MS, gas chromatography-mass spectrometry.

From Tang, Y. W. (2014). Non-genomic omic techniques. In: Tang, Y. W., Sussman, M., Liu, D., Poxton, I. R. & Schwartzman, J. D. (eds.) Molecular medical microbiology (2nd edn.). Waltham, MA: Elsevier, with permission.

**Fig. 1** Panomic techniques and their application niches in medical microbiology.

Diverse sources of *Clostridium difficile* infections were explored by comparing single-nucleotide variants between isolates which were determined by whole-genome sequencing (WGS). The data indicated genetically diverse sources, in addition to symptomatic patients, play a major part in *C. difficile* transmission (Eyre et al., 2013). Using bacterial WGS, Rossi et al. reported a case of a patient from Brazil with a bloodstream infection caused by a strain of methicillin-resistant *Staphylococcus aureus* (MRSA) that was initially susceptible to vancomycin but then acquired the *vanA* gene cluster during antibiotic therapy and became resistant (Rossi et al., 2014). Technological improvements in metagenomic deep sequencing have led to its potential application not only for basic research but also for clinical science and practice (Houldcroft et al., 2017). Metagenomics was successfully used to establish a timely diagnosis of neuroleptospirosis in a 14-year-old boy with severe combined immunodeficiency who suffered from recurrent bouts of fever, headache and coma (Wilson et al., 2014). Further study on a series of seven patients indicated that prioritizing metagenomic data with a scoring algorithm greatly clarified data interpretation and highlighted the problem of attributing biological significance to organisms present in control samples used for metagenomic sequencing studies (Wilson et al., 2018). WGS and computational analysis have been used to compare the taxonomic and functional profiles of microbial communities. Leveraging this approach to understand roles of microbes in human biology and other environments requires quantitative data summaries whose values are comparable across samples and studies. It envisioned a future in which microbiome studies are replicable and new metagenomes are easily and rapidly integrated with existing data (Nayfach and Pollard, 2016).

Transcriptomics studies the set of all RNA molecules, including mRNA, rRNA, tRNA, and other non-coding RNA, including their structures and functions (Allert et al., 2016, Holcomb et al., 2017). In *Mycobacterium tuberculosis* infections, mycobacterial mRNA better reflects viability, thereby being valuable as a reliable marker of bacteriologic clearance in response to antituberculosis therapies (Mdivani et al., 2009, Li et al., 2010). The transcriptome also includes small, noncoding RNAs, which have emerged as key regulators of gene expression, genome stability and chromatin modification (Moazed, 2009, Moller et al., 2018). High-throughput sequencing of RNA transcripts (RNA-seq), which uses next-generation sequencing technologies to generate transcriptome profiling in both pathogen and hosts (Nagalakshmi et al., 2008, Westermann et al., 2012), gradually comes into the medical microbiology research and practice. RNA-seq allows the investigation of the diverse physiologies from uncultured microorganisms in their natural habitat (Frias-Lopez et al., 2008, Bomar et al., 2011). Bomar et al. reported the use of RNA-seq for characterizing the metatranscriptome of the simple gut microbiome from the medicinal leech *Hirudo verbana* and for utilizing this information to design a medium for cultivating members of the microbiome (Bomar et al., 2011). Using a series of RNA arrays on RNA extracted from pediatric patients with sepsis, Herberg et al. identified two host transcript RNA signatures which can distinguishing bacterial

from viral infection (Herberg et al., 2016). A further study demonstrated that the 2-transcript host cell signature can distinguish viral from bacterial diarrhea and it was influenced by the severity of symptoms (Barral-Arca et al., 2018).

Proteomics is a large-scale study of the entire complement of proteins, including the modifications made to a particular set of proteins, produced by an organism or system (Tyers and Mann, 2003). The application of proteomic technology for the identification of biomarkers, altered pathways, functional alternations and mechanisms has recently been extensively reviewed (Fournier and Raoult, 2011, Meissner and Mann, 2014). Matrix-assisted laser desorption/ionization-time of flight mass spectrometry (MALDI-TOF MS) has emerged as a rapid and powerful tool for microbial species identification in the diagnostic arena (Welker, 2011, Doern and Butler-Wu, 2016). In addition, MALDI-TOF MS has been used directly to determine mechanisms of antibiotic resistance (Doern and Butler-Wu, 2016, Hrabak et al., 2013). In recent years, proteomics has emerged as a powerful tool to evaluate the complex host-response to sepsis (Sharma and Salomao, 2017). Proteomics coupled with mass spectrometry made possible to identify differentially expressed proteins in clinical samples. In recent years, a number of proteomic studies has been done under sepsis and/or in response to endotoxin and showed various signaling pathways, functions, and biomarkers (Karvunidis et al., 2009, Ludwig and Hummon, 2017). A recent study used quantitative proteomics to evaluate the host proteome response in septic patients secondary to community-acquired pneumonia. Bioinformatic analyses of differentially expressed proteins showed alteration in the cytoskeleton, cellular assembly, movement, lipid metabolism and immune responses in septic patients (Sharma et al., 2017). The proteomic results stressed important changes in cellular structure and metabolism, which are possible targets for future interventions of sepsis.

Metabolomics provides the quantitative measurement of the dynamic multiparametric metabolic response of living systems to pathophysiological stimuli or genetic modification. Over the last decades, metabolic profiling has been increasingly applied to classify diseases and diagnose onset of disease (Goodacre et al., 2004). Using metabolomic approaches, Kashyap et al. investigated how host mucus glycan composition interacted with dietary carbohydrate content to influence the composition and expressed functions of a human gut microbiome (Kashyap et al., 2013). Seymour et al. determined the global metabolomic profile in circulating plasma to differentiate between surviving and non-surviving patients with community-acquired pneumonia and sepsis (Seymour et al., 2013). Metabolomic profiles determined in serum have been reported as a novel approach for early diagnosis of pediatric septic shock and its mortality (Mickiewicz et al., 2013). Sweeney et al. presented prognostic models for 30-day mortality generated independently by three scientific groups by using 12 discovery cohorts containing transcriptomic data collected from primarily community-onset sepsis patients. Combining the new gene-expression-based prognostic models with prior clinical severity scores leads to significant improvement in prediction of 30-day mortality (Sweeney et al., 2018). Similarly, breath fungal secondary metabolite signature, determined by thermal desorption-gas chromatography/mass spectrometry, was used to diagnose invasive aspergillosis (Koo et al., 2014). When these metabolomic biomarkers are used in the clinical practice, we must remember the extreme heterogeneity of clinical illness, and strive for generalizable disease-defining diagnostics (Sweeney and Khatri, 2017). While detection of exogenous microbial volatile metabolites in the breath has opened up a new and exciting dimension of diagnostic research and development in infectious diseases, the daunting challenges to volatile diagnostic biomarker discovery and clinical development have to be kept in mind (Acharige et al., 2018).

The availability of sophisticated and increasingly inexpensive nucleic acid sequencing techniques has revolutionized the fields of genomics resulting in unprecedented advances in medical microbiology. Use of non-genomic technologies such as transcriptomics, proteomics and metabolomics allows full inventories to be made of bacterial genes, their time- and place-dependent expression and the resulting proteins as well as their outcome metabolites, thus further substantiating and broadening the medical microbiology armamentarium. What seems certain is that the advanced techniques will increasingly change and enhance the research and practice of medical microbiology.

The Bacterial Glycome: From Monomers to Complex Carbohydrate Polymers

Jochen Schmid and Volker Sieber, Technical University of Munich, Straubing, Germany

© 2019 Elsevier Inc. All rights reserved.

Introduction

The microbial and especially the bacterial glycome is defined by a vast amount of different carbohydrates and carbohydrate derivatives. These include carbohydrate monomers such as sugars, sugar alcohols, nucleotide sugars as well as keto and deoxy sugars, followed by di- to oligosaccharides, lipopolysaccharides and polysaccharides. Additionally, the peptidoglycan layer of bacterial cell walls as well as the murein sacculus are part of the bacterial glycome which also includes glycosylated proteins. Based on these facts, it is obvious that research and analysis of the bacterial glycome (glycomics) represent one of the highest complex omics sections of bacterial systems and is also demonstrated by the versatile functions of the different carbohydrate-based and glycosylated molecules. Glycomics, therefore, are defined here as the study of glycoconjugate assembly and their functions in biological systems.

Sugar nucleotides are the most essential precursors for the biosynthesis of various carbohydrate-containing bacterial cell structures, which are important virulence factors of pathogenic bacteria. In the majority of the cases, they function in the evasion of the bacteria from the host immune system. Other sugar-containing structures, like peptidoglycan, have important roles in bacterial viability. In addition, some of these structures and their biosynthetic pathways are being regarded as attractive targets for the development of new antimicrobial drugs. Some sugar polymers are applied in the food, pharmaceutical, textile and paper industries, thus having important economical significance. Therefore, the study of metabolic pathways responsible for polysaccharide and precursor synthesis, as well as their regulation, is of critical importance for the optimization of microbial production processes of carbohydrate-containing polymers.

Monosaccharides and Carbohydrate Derivatives

For the monosaccharides, the main representatives in the glycome are the aldoses glucose, galactose and mannose (Fig. 1A) as well as ribose and glyceraldehyde but also ketoses such as fructose and erythrose are of importance. Next to the monosaccharides, sugar alcohols play an essential role in cellular metabolism and the glycome and comprise molecules such as glycerol, mannitol or sorbitol (Fig. 1B). From an industrial point of view, sugar alcohols are an interesting alternative to sugars, due to their usually incomplete absorption into the blood stream from the small intestine which generally results in a smaller change in blood glucose than “regular” sugar (sucrose). Thus, they are often used as sweeteners in low-carb and diabetic diets.

Deoxy sugars are characterized by replacement of a hydroxyl group with a hydrogen atom and are a constituent of DNA in the case of deoxyribose but can also be part of complex polysaccharides such as fucoidan which is synthesized by polymerization of fucose, which as a monomer can also participate in protein N-glycosylation. Another deoxy sugar is rhamnose (Fig. 1D) which can be found in many plant glycosides or bacterial polysaccharides. Additional acidic variants of monosaccharides exist in the form of uronic acids, which are a class of sugar acids with both carbonyl and carboxylic acid functional groups (Fig. 1C). For them, the terminal carbon hydroxyl group has been oxidized to a carboxylic acid and they function as main constituents of bacterial exopolysaccharides such as alginate or several further heteropolysaccharides.

Another piece of the glycome are the nucleotide sugars which are the activated forms of monosaccharides and play a crucial role in cell metabolism and regulation and represent the glycosyl donors in glycosylation reactions. Their highly energetic form makes them the perfect glycosyl donor and is realized by the result of a reaction between nucleoside triphosphate (NTP) and glycosyl monophosphate (Fig. 2). In the bacterial glycome nearly all kinds of nucleotide sugars appear and are involved in several cellular reactions and are required for the synthesis of nearly all carbohydrate containing oligomers and polymers.

GDP-mannose for example is the donor of D-mannose which is a sugar residue found in many bacterial polysaccharides such as Xanthan or sphingans (Fig. 3). GDP-D-rhamnose is a more rare deoxyhexose and is mainly found in the lipopolysaccharides of pathogenic bacteria, but also some exopolysaccharides such as the different sphingans. Additionally, rhamnose can be found in the S-layer of some thermophilic Gram-positive bacteria. GDP-L-fucose can be found in many glycoconjugates of microbes, but also plants and animals. Fucose often represents a part of complex cell-wall structures, lipopolysaccharides and like rhamnose its function is related to interactions of the bacteria with host tissue, and to mask the bacterial cells from the host immune system. GDP-mannuronic acid is the precursor for mannuronic acid and guluronic acid since it can be easily epimerized by specific epimerases and is the main constituent of the polysaccharide alginate. Its acidic character makes it interesting for various applications, such as biomedical wound healing in the form of hydrogels.

dTDP-L-rhamnose is mainly found as precursor for O-antigens of lipopolysaccharides in many Gram-negative bacteria, where the O-antigen repeating units is mainly composed of rhamnose. The synthesis of L-rhamnose needs four enzymatic steps, and the genes encoding these enzymes can often be found clustered in the genome. The intermediate dTDP-4-keto-6-deoxy-D-glucose is the

Fig. 1 Examples of carbohydrate monomers and their derivatives. (A) The sugar monomer of *D*-mannose; (B) The sugar alcohol *D*-mannitol; (C) The uronic acid *D*-mannuronic acid; (D) The deoxy sugar *D*-rhamnose (deoxy-mannose).

Fig. 2 Mechanism of the synthesis of activated nucleotide sugars. A monosaccharide reacts with a nucleotide triphosphate by release of a diphosphate, resulting in the high energetic nucleotide sugar.

Fig. 3 The activated form of mannose as presented by GDP-mannose. The C1 of the mannose monomer is linked to the nucleotide diphosphate.

precursor for many compounds that are part of antibiotic glycosides. This biosynthesis pathway for dTDP-rhamnose is unique in bacteria and does not exist in humans, thus offering a potential target for antimicrobial agents.

UDP-D-glucose is the main constituent of various bacterial sugar containing bacterial structures, such as peptidoglycan, lipopolysaccharides and exopolysaccharides. Additionally, UDP-D-glucose is the substrate for glycosylation of teichoic acid in Gram-positive bacteria as well as the membrane anchor of lipoteichoic acids, which is made of the glycolipid diglucosyldiacylglycerol. It serves as the direct precursor for (bacterial) cellulose and as initial precursor for other exopolysaccharides such as hyaluronic acid by its further conversion to UDP-glucuronic acid. D-glucuronic acid might play an important role in bacterial resistance against antibiotics, since the enzyme converting UDP-glucose towards UDP-glucuronic acid seems to be essential for the resistance. UDP-D-galactose is the substrate for many galactose containing exopolysaccharides and glycoproteins. UDP-N-acetylglucosamine is used for the assembly of the cell wall peptidoglycan, lipopolysaccharides as well as teichoic acid and can be further converted

towards UDP-N-acetyl-D-mannosamine which serves as precursor for Sialic acid biosynthesis which plays an essential role in many capsular polysaccharides of pathogenic bacteria by masking the bacterial cells from the host immune system. An overview of the different nucleotide sugars and their biosynthesis routes is given in Fig. 4(A). Next to the monosaccharides and derivatives thereof, oligosaccharides exist in the bacterial glycome, which mainly are part of protein glycosylation.

Fig. 4 A schematic overview of the parts of the glycome including their localization within the cell. (A) Schematic biosynthesis pathways of the different nucleotide sugars (orange rectangles) and their precursor carbohydrates (green elapses). The different conversion steps are performed by a huge variety of highly specific enzymes. (B) Scheme of the peptidoglycan which is located in the periplasmic space in between the inner membrane (IM) and the outer membrane (OM). The peptidoglycan consists of N-acetylglucosamine (dark blue) and N-acetylmuramic acid (orange). Each N-acetylmuramic acid is linked to another N-acetylmuramic acid in the attached layer via a peptide chain of three – five amino acids (grey bonds). (C) schematic presentation of the teichoic acids which are vertically incorporated into the thick peptidoglycan (yellow) of Gram-positive bacteria. They are covalently linked to N-acetylmuramic acid, or to a terminal alanine of the peptide crosslink. When they are anchored in the inner membrane via a lipid linker, they are called lipoteichoic acids. The most common structures of teichoic acid are disaccharide repeating units of N-acetylmannosamine and N-acetylglucosamine. (D) schematic biosynthesis machinery of capsular exopolysaccharides (CPS) which spans the whole cell envelope from inner to outer membrane. The CPS is anchored to the lipid linker via 2-keto-3-desoxy-octonate (red squares) and is synthesized at the cytoplasm and then transported via the ABC-transporter towards the environment assisted by polysaccharide co-polymerase (PCP) and outer membrane proteins (OPX). CPS remain linked to the cell and are heteropolysaccharides as schematically represented by the different colours of the sugar monomers. (E) schematic biosynthesis of the Wzx/Wzy dependent pathway which is characterized by the assembly of the repeating units at the inner leaflet of the inner membrane via different glycosyltransferases and transport to the periplasmic space via the flippase protein Wzx (not shown). Assembly of the repeating units occurs via the polymerase (Wzy) and polysaccharide co-polymerase protein (PCP) and following transport of the heteropolysaccharide to the environment via OPX proteins (a). The synthase dependent pathway (b) is characterized by assembly of homopolysaccharides via the synthase complex and assisted transport via the tetratricopeptide repeat proteins (TPR) spanning the cell envelope. (F) protein glycosylation via transfer of repeating units assembled at the inner membrane (at a dolichol anchor) and flipped towards the periplasm where the repeating unit is attached to the specific amino acid sequence of the protein (a). Sequential glycosylation at the cytoplasm followed by transport of the glycosylated protein to the periplasmic space (b). (G) S-layer of Gram-negative (a) and Gram-positive bacteria (b). The proteins (orange) are linked to lipopolysaccharides (a) of the outer membrane, or directly to the thicker peptidoglycan layers of Gram-positive bacteria (b). (H) lipopolysaccharides (LPS) consist of the Lipid A, which is part of the outer leaflet of the outer membrane, the inner core region (a) and the outer core region (b), which consist of KDO and heptoses and hexoses (purple) of non-homogenous variation. The O-antigen (c) consists of different carbohydrate monomers (glucose, rhamnose...) as well as dideoxy sugars.

The Bacterial Cell-wall

Additionally, all Gram-negative bacteria exhibit a cell envelope of the same general architecture which is schematically depicted in Fig. 4(B). The periplasmic “space” is the space between the inner and outer membrane and contains peptidoglycan, also known as murein, as a major constituent. This macromolecular sacculus is composed of sugar chains built from alternating 2-acetamido-2-deoxy-D-glucopyranose (GlcNAc) and 2-acetamido-3-O-[(R)-1-carboxyethyl]-2-deoxy-D-glucopyranose, also termed N-acetylmuramic acid (MurNAc). These carbohydrates represent residues which carry and can be cross-linked by smaller peptides – The amino acid composition of which varies in different species. The peptidoglycan sheet represents a rigid layer that determines the form of the bacterial cell, reinforces the osmotic stability and acts as a protective barrier. However, the murein sacculus is not a completely closed barrier, since it still enables the transport of small molecules, such as nutrients or excretion of metabolites via for e.g., primary and secondary transporters. Only a very limited number of bacteria, mainly belonging to the genera *Mycoplasma* and *Spiroplasma*, do not possess a murein sacculus.

Lipopolysaccharides

Lipopolysaccharides are a combination of lipids and polysaccharides at the outer membrane of Gram-negative bacteria. They are recognized as antigens and can be used for the serological characterization of bacteria. In the case of cell death, the lipopolysaccharides fall apart and show their toxic function.

Lipid A is at the outer leaflet of the outer membrane and functions as endotoxin. The fatty acid is linked by ester bonds to a disaccharide which consists of N-acetylmuraminephosphate. Main fatty acids are capron, lurin, myristin, palmitin and stearin acid. The core region of LPS consists of the 2-keto-3-desoxy-octonate (KDO) linker and heptoses, glucose, galactose and N-acetylglucosamine (Fig. 4(Ha+b)). The sugar pattern of the core region can remarkably differ within the various bacterial species. The O-antigen polysaccharides consist of several hexoses, such as rhamnose, galactose, glucose and mannose, as well as rare dideoxy sugars such as abequose, colitose, paratose or tyvelose which can carry additional modifications and decorations and can contain several branches. The sequence is made from repeating units which are form the polysaccharide. This polysaccharide is named O-antigen and can be used to distinguish between pathogenic and non-pathogenic strains by serotyping. Due to its localization on the cell surface, the O-antigen is a major target for both the immune system as well as bacteriophages and represents one of the most variable cell constituents (Fig. 4(Hc)). Very interestingly, the biosynthesis machinery of O-antigen encoding genes are clustered in the genome and are highly conserved within a species. The O-antigen carbohydrate part mainly consists of oligosaccharide repeating units in the range of 2–8 sugars from a highly broad monomer composition. The lipopolysaccharides also present an important virulence factor which can be serotyped by its specific monomer composition. One important aspect of the O-antigens of lipopolysaccharides is their heat stability compared to other O-antigens, which are mainly heat-labile. The serotyping based on lipopolysaccharides was already performed in-between 1945 and 1950 for various *Escherichia coli* strains and was one of the mostly applied techniques in the identification of pathogens. The K-antigens in contrast are mainly composed of polysaccharides and stuck to the cell envelope, thus hindering the agglutination of the cells. The K-antigens are a synonym for capsular polysaccharides and have an even higher diversity than the O-antigens and are the major virulent determinants of Gram-negative bacteria. Based on this fact structural databases for the 3-D structures exist e.g., for *E. coli*, but also pathogens such as *Klebsiella pneumonia* and are in the focus for enabling a targeted identification of pathogenic strains. Taking all antigens of *E. coli* together, there will be around 50,000–100,000 serotypes, showing the immense diversity, realized by sugar composition and glycosidic linkages. The capsules are molecules of 100–1000 kD multimers, which are assembled by repeating units, and thus enables the prediction of the 3-D structures as well as the monomer composition.

Gram-positive bacteria are defined by their thicker murein sacculus compared to Gram-negative bacteria but lack the outer membrane (Fig. 4(C)). An additional reinforcement of the cell wall is realized by incorporation of teichoic acid, which is unique to Gram-positive bacteria. Teichoic acid is composed of mainly N-acetylmannosamine (ManNAc) and N-acetylglucosamine (GlcNAc) directly linked to glycerol- or ribitol phosphate. Teichoic acid can attract cations and thus has the function of providing rigidity to the cell wall as a co-polymer and as part of the bacterial glycome.

The so-called S-layer represents the outer layer of the cell wall of many bacteria and the only one in the case of certain archaea. It consists of layered (glyco)proteins which are organized by a self-assembly like process (Fig. 4(G)). The S-layer contains glycosylated as well as non-glycosylated proteins and can act as virulence factor in some species, such as *Campylobacter*. Thus, it is obvious that the cell wall structure is highly complex and can vary massively between different genera and species. But for all of them, carbohydrates and their derivatives are the most abundant compounds of the cell wall and play essential roles in cell communication and pathogenicity of microorganisms.

Protein Glycosylation

Protein glycosylation was first demonstrated in the late 1930s and was long thought to exist only in eukaryotes, but glycosylation is the most abundant polypeptide chain modification in nature, also in bacteria. By that approach glycans can be covalently attached to the amide nitrogen of asparagine residues (N-glycosylation), to the hydroxyl oxygen of, typically, serine or threonine residues (O-glycosylation), or, in rare cases, to the indole C2 carbon of tryptophan through a C–C linkage (C-mannosylation).

The first bacterial and archaeal glycoproteins were discovered in the 1970s on the S-layers of *Halobacterium salinarum* and *Clostridium* sp. by O-glycosylation. It took more than 20 more years to identify the first N-linked protein glycosylation in *Campylobacter jejuni* and step by step more glycosylating pathways were identified, based on the development of more sensitive detection methods, such as next generation sequencing and sophisticated mass spectrometry techniques. The N-glycosylation of *C. jejuni* follows the heptasaccharide formation on an undecaprenyl phosphate anchor at the cytoplasmic side of the inner membrane. This heptasaccharide unit is then flipped towards the periplasmic space by an ATP-dependent flippase and transferred to asparagine residue of the targeted protein by an oligosaccharyltransferase (Fig. 4(Fa)). The bacterial N-glycosylation uses a different consensus sequence (Glu-X-Asn-X-Ser/Thr, with X can be any amino acid except proline) of the protein, to specifically find the right asparagine, than the eukaryotic system (Asn-X-Ser/Thr, with X can be any amino acid except proline). Next to the transfer of repeating units, glycosylation can also occur by a sequential transfer of single sugar monomers in the form of their activated nucleotide sugars (Fig. 4(Fb)). The functions of bacterial protein N-glycosylation are not completely understood but might range from stabilizing the enzyme to the modulation of immune response in pathogenic microbes. O-glycosylation can be often found in modification of bacterial flagella and pili, in that the glycosylation can constitute up to 10% of the protein mass. Bacterial O-glycosylation is of main importance for flagellum assembly, secretion of virulence modulating proteins, bacterial colonization of the gastrointestinal tract, auto-agglutination as well as biofilm formation. The O-glycans of the *Campylobacter* flagellum are mainly C9 sugars, such as pseudoaminic or legionaminic acid and use mainly GDP-linked intermediates in contrast to the UDP-linked intermediates for the N-glycosylation. As for N-glycosylation, the sequential transfer as well as the block transfer are described in different bacteria. The glycosylation pathways are encoded in genomic islands and more and more sequences get identified by massive genome sequencing approaches. The main targets for O-glycosylation are serine or threonine residues with various consensus sequences. Another widespread protein glycosylation pattern is the O-mannosylation in Gram-positive actinomycetes, which is found in several bioactive products and secreted antigens.

Exopolysaccharides

Exopolysaccharides can occur as homopolysaccharides, by polymerizing only one type of activated sugar monomer such as bacterial cellulose, or in the form of heteropolysaccharides, with alternating sugars or sugar derivatives in their chemical structure. They are assembled by different mechanisms which will be explained in brief here.

In the case of homopolysaccharides, most of the bacterial exopolysaccharides are produced by a synthase complex, which starts from the activated form of the sugar or sugar derivatives at the cytoplasm, by transferring one monomer towards a nascent growing chain of the polymer (Fig. 4(Eb)). This type of biosynthesis is used for cellulose, by forming a beta-1,4-linked glucose-containing polymer, and is also responsible for the production of alginate by firstly assembling a pure mannuronic acid homopolymer by utilization of GDP-mannuronic acid as precursor. By the transport across the cell wall towards the extracellular environment, various epimerases which are integral part of the biosynthesis machinery can specifically convert mannuronic acid (M) towards glucuronic acid (G) in the polymer strand. One famous exception of a synthase-based biosynthesis pathway encoded polysaccharide is hyaluronic acid. This polysaccharide, which has a high importance in cosmetic applications due to its enormous water binding capacity, consists of the repeating disaccharide unit of D-glucuronic acid and N-acetyl-D-glucosamine. The biosynthetic pathway is encoded by five genes, the products of which assemble the final polymer strands, resulting in a heteropolysaccharide based on a synthase based biosynthetic pathway.

In the case of heteropolysaccharide production, two different pathways are mainly found. These are the so-called ABC transporter pathway, as well as the so-called Wzx/Wzy-pathway. Since it is already seen by the examples for lipopolysaccharides and capsular polysaccharides, the insights are not always clearly understood, and the definition of CPS and EPS might vary within different disciplines. For the capsular polysaccharides, mainly the ABC transporter dependent pathway is described, which uses the KDO-linker to produce a growing polymer chain by adding specific repeat units (Fig. 4(D)). The activated monomers are transferred by specific glycosyltransferases in the cytoplasm and the chain is then actively transported over the cell wall via an ABC transporter by utilization of ATP. The second, and main abundant biosynthesis pathway for heteroexopolysaccharides is the Wzx/Wzy-pathway. This pathway uses an inwards-faced polyprenol (dolichol) anchor at the inner membrane, to sequentially transfer activated sugar monomers by the action of various specific glycosyltransferases. This anchor will finally carry the completed repeating unit and is then flipped by the Wzx protein towards the periplasmic space. The next steps are the polymerization of the repeating units by the polymerase protein Wzy followed by transport across the cell wall towards the environment (Fig. 4(Ea)). This biosynthetic pathway also includes co-polymerases which are involved in chain length determination of the final exopolysaccharide strands, which are not covalently linked to the cell. All three pathways as described here are highly specific for the monomer pattern of the polysaccharides, but the chain length of the polysaccharides can vary by the cultivation conditions. For alginate it is also described that the cultivation conditions, such as mixing speed and dissolved oxygen content can influence the M:G ration of the final products. For some exopolysaccharides it is also described that the C- or N- source can influence the monomer pattern of the polysaccharide. But it must be kept in mind that around one fifth of bacteria and archaea encode more than one specific pathway for the biosynthesis of capsular polysaccharides or exopolysaccharides, thus the cultivation conditions might more influence the transcription of different polysaccharide encoding operons than the specific biosynthesis itself. This was clearly demonstrated in *Sinorhizobium meliloti*, which encodes biosynthesis pathways for two different exopolysaccharides, EPS I (succinoglycan) and EPS II (galactomannan) in its genome, and EPS II is just produced under phosphate limitation, whereas EPS I is produced also at high

phosphate concentrations. The choice of C-source can also influence the type of polysaccharide which is produced, since there exists another biosynthesis pathway which was not discussed here yet. This pathway uses a single enzyme, which is located at the S-layer of the cell wall and can cleave disaccharides to produce mainly homopolysaccharides by utilizing the energy obtained by cleaving the glycosidic bond. These enzymes are the so-called levan- or dextran sucrose enzymes and can produce levan or dextran respectively. Thus, this biosynthesis is the sole extracellular polysaccharide biosynthesis found in bacteria. Dextrans and levans are mainly produced under stress conditions of the microbes and solely in the presence of sucrose or other di- or trisaccharides. These polysaccharides are branched and can be produced of different molecular weights. In general, the regulation of microbial exopolysaccharide production is not fully understood and can be of high complexity by recruiting networks and cascades of integrated regulatory processes, such as two-component signal transduction systems, transcriptional as well as posttranscriptional regulation as proven for the well examined biosynthesis of alginate in *Pseudomonas fluorescens*. Further regulation, which seems to be widespread amongst many bacterial exopolysaccharide producers is positively linked to enhanced c-di-GMP levels, which promotes exopolysaccharide production and more and more insights are obtained to evoke silent gene clusters for exopolysaccharide production by enhanced c-di-GMP levels.

Analytics of the Glycome

Novel analytic techniques to analyse the bacterial glycome have massively improved our understanding of the carbohydrate-based world of bacteria. Sugar analysis can be done by high-performance liquid chromatography (HPLC) or gas chromatography (GC), whereas HPLC is mainly used to distinguish the single monosaccharides and GC is used to unravel specific glycosidic bonds via methylation experiments. Very often both methods are coupled to a mass spectrometer which additionally allows the differentiation of overlapping peaks via mass analysis. Highly sophisticated methods, in combination with optimized protocols led to shortened and high-throughput capable methods for the analysis of monosaccharides, oligosaccharides as well as polysaccharides within the last years. Also, the analysis of sugar derivatives is realized via HPLC and GC. Both methods enable the analysis of monomers or dimers and sometimes oligomers, when reliable standards are available, but mostly come to their limits when the complete chemical structure of highly complex polysaccharides must be elucidated. Nuclear magnetic resonance (NMR) analysis can help to obtain insights into the chemical structure by analysing the resonance frequencies of the neighbouring nuclei present in the polymers, but this method is sometimes limited by the high viscosity of microbial polysaccharides and hindered by the high concentrations as necessary for NMR analysis. Another possibility to identify specific antigens, lipopolysaccharides or polysaccharides is the utilization of lectins. This class of carbohydrate-binding proteins is highly specific for a defined sugar moiety and perform recognition on cellular and molecular level. Several techniques have been established for using lectins in microarray based-approaches for the targeted identification of glycans and glycoproteins, which massively improved our understanding of the bacterial glycome. For the identification of glycosylation patterns of proteins, specific proteases are used to cleave the glycosylation from the protein and analyse it by mass spectrometry or other techniques. These sophisticated methods require advanced computational and database infrastructures to analyse and elucidate large-scale data. Therefore, the field of glycoinformatics is rapidly developing and has advanced scientific inquiry in the field of glycome analysis.

Outlook

As described in this article, the bacterial glycome is a highly complex system, which is based on carbohydrate chemistry. Our insights are still limited but with the application of novel techniques, mostly in the field of genome sequencing, metabolic engineering in close connection with highly sensitive analytical methods, we are on a good way towards a better understanding of the carbohydrate-based world of bacteria. These insights might bring new products on the market, such as natural noncaloric sweeteners, beneficial sugar alcohols, oligosaccharides with pre-biotic activity, polysaccharides with a broad range of medical as well as technical applications and a huge amount of targeted stabilized glycosylated enzymes which can be applied in industrial processes, based on their enhanced thermostability or pH-acceptance. These are only some examples of how the bacterial glycome can contribute to a biobased industry. Further, also new production strains can be developed by a better understanding of the glycome.

The Evolutionary Ecology of Microbes

Sara Mitri, University of Lausanne, Lausanne, Switzerland

© 2019 Elsevier Inc. All rights reserved.

Introduction

Antonie van Leeuwenhoek was the first to report on observing microbes. His writings describe many different “sorts” of “little living animalcules” that he observed in dental plaque. The recent revolution in sequencing technology has confirmed that indeed, most sampled environments whether the petals of a flower, a drain pipe or human skin, contain hundreds of co-existing species. Nevertheless, most of our current understanding of microbiology has come from studying clonal cell cultures in laboratory test tubes. Microbial ecology, and even more so, the evolutionary ecology of microbes is a relatively young field.

There are three main approaches to studying how evolutionary and co-evolutionary processes shape microbial communities: the first is through DNA sequencing and genomic analysis of environmental samples, possibly sampled over time; second, simulating community evolution in the lab using synthetic microbial communities composed of few, known species under controlled conditions; and finally, through *in silico* modelling of these processes using digital organisms. Sequencing microbial DNA extracted from their natural habitats does not just reveal their current ecology, but also the outcome of their evolutionary history: the individual species and the community as a whole have been shaped by many years of natural selection. The environment selects for species that are able to survive in it, adapt to it and outcompete their neighbours. In turn, any newly arrived species may alter the environment and interact with and affect their neighbours, thereby triggering new rounds of selection and adaptation. It is the result of this co-evolutionary process that we capture in a snap shot of an environmental sample. In contrast, while synthetic microbial communities may differ radically from natural communities, controlling their environment allows researchers to follow individual species, their abundances and their mutations over time. In addition, since samples from different time-points can be frozen and revived, the approach allows for comparing geno- and phenotypes along their evolutionary history. Finally, mathematical and computational models of microbial life allow to test general theories and hypotheses, while compromising further on realism.

All of these approaches have answered important research questions according to which the article is organized: first, I describe what we know about microbial species diversity in natural environments and how we define microbial species; second, I discuss mechanisms by which microbes can adapt to the selection pressures they are subjected to; third, I outline what we know about how microbes interact with one another, imposing a different kind of selection pressure and why this is difficult to quantify; and finally, I discuss how we can explain the diversity that we observe and how it is maintained. Throughout the article, I take a biased view of microbes and focus mostly on bacteria, although archaea, eukaryotic microbes and viruses are also mentioned. This is not a comprehensive review, but rather a discussion of the main ideas in the field.

Microbial Populations are Highly Diverse

Species Diversity in Natural Microbial Populations

In some environments, microbes live within clonal groups of cells. This is the case for some host-associated bacteria, such as *Vibrio fischeri*, a bacterium that grows inside a specialised organ of the Hawaiian bobtail squid, *Euprymna scolopes*. By producing luciferase, the bacteria illuminate the organ of the squid, camouflaging it from its predators. Since squid and bacteria appear to have co-evolved for this function, the squid tightly monitors access to its light organ, only letting in bacteria that perform that specific function. Similar systems have evolved elsewhere, such as nitrogen-fixing bacteria growing in legume nodules, or fungi farmed by ants as an antibacterial. Another common clonal lifestyle are bacteria that live inside eukaryotic cells, as is common in insects. While these are fascinating examples of cross-kingdom cooperation, single microbial species that are tightly controlled by a host to perform a specific function are probably the exception.

For the vast majority of microbes, life is spent within highly diverse populations that cover virtually every surface on earth. This includes our own – and other mammals’ – bodies: *e.g.*, skin, intestines, oral cavity, and lungs; plant leaves, flower petals, and roots; man-made artefacts, unfortunately including medical equipment; soil consists largely of microbes; and we find microbes growing on particles in lakes and oceans, and even in raindrops. Our knowledge of this diversity comes from our ability to extract DNA from these environments, to sequence it at ever decreasing costs, and to identify microbial DNA. Carl Woese and colleagues revolutionized microbial ecology by developing methods to sequence 16S ribosomal RNA genes that are present in bacteria and archaea – which they discovered to be the third branch of the tree of life – and 18S genes in eukaryotic microbes. Because these genes are well-conserved, they are well-suited to inferring phylogenetic relationships between microbial strains. Compared to the naturalist’s approach of classifying species by phenotypes, this approach of classifying microbes into “operational taxonomic units” (OTUs) based on their similarity at one locus has accelerated and scaled up identification enormously. Today, at very low effort and cost, one can quickly get a broad idea of the hundreds of microbial OTUs present within a sample. Nevertheless, defining microbial species is by no means straight-forward.

The Species Concept in Microbes

Species classification based on 16S genes is flawed for one main reason: Even though microbes divide clonally, not all their genetic material is passed on between parent and offspring cells. Instead, a large portion of their genome is acquired “horizontally”, from non-clonal cells. So-called Horizontal Gene Transfer (HGT) or Lateral Gene Transfer (LGT) occurs through three general mechanisms: direct passing of genetic material between two connected cells (conjugation), transfer through a third party such as a virus (transduction), or by taking up DNA from the environment (transformation). Current estimates of the average number of genes in a bacterium that have been horizontally transferred at some point in its evolutionary history approximate to 80%. This means that even if two bacteria have very similar 16S genes, they may differ at many other loci, and exhibit completely different phenotypes. A good example is *Escherichia coli*, a model bacterial species that can live in various different environments, and from a human perspective, can be either a harmless commensal or a deadly pathogen. This stands in contrast to the eukaryotes, where species identity correlates closely with an organism’s phenotype, and reduces the utility of bacterial species classification by 16S. In this article, I therefore refer to “genotypes” rather than “species” to avoid the somewhat arbitrary cut-offs of 16S gene similarity. Nevertheless, because genetic inheritance still mostly occurs vertically, and because HGT is more likely to occur between closely related species, 16S sequencing remains the most practical and informative approach for describing multi-species microbial communities.

Whole genome sequencing and analysis of bacterial genomes has revealed much about their structure and how they have been shaped by ecology and evolution. In particular, it has allowed for the identification of areas of the genome that are more static and others that evolve more quickly, through mutation or HGT. Genes that are present in all genomes of a particular species (identified based on 16S gene similarity) are classified as “core”, while those that vary in at least one sequenced strain of that species are “accessory”. The totality of core and accessory genes present in a species or clade is its “pan-genome”. The goal of this approach is to predict which core genes are absolutely necessary for survival and cell division, and which accessory genes are rather environment-specific. Genes for antibiotic resistance, for example, are likely to be part of the accessory genome, since they are only needed when antibiotics are present. A useful analogy that has been proposed to help think about microbial genomes, is that the core genes represent the operating system of a smart phone, while the accessory genes represent the applications that can be downloaded onto the phone as needed.

Microbial Adaption to the Environment

Mechanisms for Generating Variation

There are two ways in which microbes can generate genetic diversity, allowing them to adapt to their local environment: through mutation or horizontal gene transfer (HGT). Mutations include single nucleotide modifications, as well as larger changes, such as deletions, duplications and movements of large sequences within the genome. The rate at which mutations occur can vary widely. While in most cases, mutations are quite rare, bacterial response to stress can trigger the emergence of “hypermutators” that have a mutation rate that is orders of magnitude higher than the wildtype. This increases the chances of acquiring a mutation that will allow them to survive in a new environment, while simultaneously being prone to mutations with negative fitness effects that may lead to death. Indeed, experiments using *Escherichia coli* have shown that of the mutations that occur in hypermutators, the majority appear to be neutral, with more deleterious than beneficial mutations. This gambling strategy at the individual level may pay off at the population level: from an initially clonal group of cells, only few need to acquire the beneficial mutations required in the new environment, resulting in successful colonization. Alternatively, adaptation to novel environments often occurs through gene duplication, thereby conserving the original function of the gene and allowing mutations to accumulate on the new copy, leading to additional functions. This process is called “neofunctionalization”.

HGT is the second important mechanism by which innovation can occur on arrival in a new environment. A well-known example is the acquisition of antibiotic resistance genes on arrival in an environment containing antibiotics. These newly acquired genes may of course have detrimental effects on their host, and in particular, often carry a fitness cost by slowing down growth due to the expression of additional genes. To avoid this cost, genes on horizontally transferred elements can further adapt within the organism through mutation to be more compatible with its expression profile and reduce their cost.

Finally, migration of genotypes into novel environments provides new variants for selection to act on. Microbes often migrate through flowing liquids, or aerosols, but can also form resistant spores that can persist in dry environments and experience revival when returned to a liquid environment. One of the canonical ideas in microbial ecology and biogeography highlights the role of migration: “everything is everywhere, but the environment selects”. Although this idea is frequently cited, infinite dispersal of all species across the globe is clearly an oversimplification. Nevertheless, the principle is useful in highlighting the importance of dispersal and environmental selection on observed genotypes.

Selection by the Environment

Variation generated through the above-listed mechanisms is then purged through selection, since genotypes that are able to survive and replicate in an environment are more likely to become its long-term residents. Nevertheless, the extent to which microbial

communities are shaped by selection compared to drift remains an open question. This question can be asked at two levels: to what extent selection shapes species composition on the one hand, and the genomes of individual microbes on the other.

First, then, does selection or drift shape species composition? Are species found in a particular environment the ones best adapted to it, or did they land there by random chance and are barely surviving? Indeed, surviving in a new environment is likely to be extremely challenging. An incoming species must compete with resident microbes, it must resist predation by protists, bacteriophage (viruses), and macrophages in the case of a mammalian host, and it must survive other environmental conditions, such as salinity, pH, humidity, etc. The habitat filtering model – a classical concept in ecology – proposes that such harsh environmental conditions impose “filters” for incoming genotypes. Those that are unable to survive in it would either quickly die out or adapt. This view proposes selection as the dominant force shaping communities. If this is indeed the case, one would expect to mostly find similar “core species” in each type of environment, with few “accessory species” that are unique to some samples but not found in other environmental samples of the same type.

Consistent with the importance of selection in shaping communities, microbial species identity in human body sites of different individuals (e.g., bacteria in the oral cavity), are more similar to each other than body sites within the same individual (e.g., bacteria in the oral cavity versus the skin of the same person). Similar analyses have been conducted on the microbiomes of different organisms, which were found to differ in the similarity of their communities. The honeybee gut, for example, typically contains the same handful of species across the globe, while the microbiome of the fruit fly *Drosophila melanogaster* varies widely depending on their diet.

The second part of the question focuses on the genomes of these surviving organisms: to what extent are their accessory genes (that differ from the same species in a different environment) adaptive or the consequence of neutral drift? Some genes may be subject to millions of years of selection, whereas others may have hitchhiked along. As a rule of thumb, genetic drift is stronger for small population sizes and weaker selection. One can even measure which genes are important for a given organism in a given environment by mapping out its fitness landscape, i.e., the contribution of different genetic changes to its fitness. This can be achieved by a recently developed technique called TnSeq, where random mutations are applied all over the genome and the surviving genotypes sequenced to assess which genes are important. Gene importance can then be compared across environments to distinguish environmentally specific genes. Other methods include comparing gene expression or protein production in different environments or analysing mutational patterns.

A clear signal of how microbial genomes have evolved as a consequence of their ecology is genome size. It is now well-established that free-living microbes have significantly larger genomes than intracellular microbes. Indeed, versatile microbes capable of surviving in several different environments tend to have larger genomes than specialized microbes, such as the marine cyanobacterium *Prochlorococcus*, which is known to have a particularly small genome. At the extreme end of small genomes lie bacteria living inside a host's cells. These have very minimal accessory genomes and are subject to fewer HGT events compared to their free-living relatives. The reduction in genome size is largely due to their small effective population sizes, which lowers the efficiency of natural selection.

Competition and Cooperation Between Microbes

An integral part of the environment in which a microbe arrives are its resident species. The way in which it interacts with these residents is paramount to its survival in its new community. Such interactions are of three broad types: positive, negative and neutral, describing how the presence of one genotype affects the growth and survival of another. One proposal has been that microbial interactions are typically weak or neutral, which is hypothesized to stabilize communities.

Are Interactions Accidental or Adaptive?

When species do affect each other, these effects may occur accidentally, for example, where two species requiring the same nutrient sources to grow compete with one another. Positive accidental effects may also occur if the waste products of one species provide nutrients to another – known as “cross-feeding” – or improve the environment, for example, by altering the pH to be more favourable for its neighbour. On the other hand, some phenotypes appear to have been selected because of their effect on others. A good example is the secretion of antibiotics or other toxins that inhibit the growth of another or even kill it. Similarly, type VI secretion systems are used in lethal competition with other genotypes. Many cooperative phenotypes have also been observed that are likely to have evolved for that purpose. A classic example is the secretion of siderophores into the environment, allowing the secreting cells as well as their neighbours to harvest insoluble iron that is necessary for growth. Such cooperation typically occurs within genotypes, although some examples of between-species cooperation have also been observed.

The Challenge of Classifying and Quantifying Interactions

Measuring and classifying interactions between microbes is a big challenge, particularly in complex communities. Two approaches have been taken to measure interactions in genomic samples extracted from natural microbial communities: the first is to search for patterns of co-occurrence between species, with the assumption that if two species never co-occur, this may be because they outcompete each other, while co-occurring species may be candidates for positive interactions. Unfortunately, however, this does

not allow one to distinguish interactions from a habitat filtering model. The second approach is to follow the dynamics of a single community over time and search for correlations in growth patterns of the different genotypes. By fitting models to these co-varying population densities, one can estimate interaction coefficients. This approach similarly suffers from the inability to distinguish between-genotype interactions from a scenario where multiple species respond simultaneously to changes in the environment. Measuring interactions in a complex community remains a major challenge.

Smaller communities made up of few genotypes that can be cultured in the lab are instead more amenable to interaction classification. In particular, growing species alone and with a given partner genotype and comparing growth patterns is a reliable way to quantify interactions. However, these may change with environmental conditions, particularly when the species are no longer in their artificial laboratory habitat. Moreover, distinguishing accidental effects on another versus effects that have evolved for that purpose is also challenging. In sum, we are still far from understanding interaction patterns in microbial communities.

The Maintenance of Species Diversity

A long-standing question in microbial ecology is why we observe so many species and strains in the majority of sampled environments. Despite predictions that competing genotypes should drive each other extinct, a single gram of soil is estimated to contain thousands of species, suggesting that there must be mechanisms preventing such competitive exclusion. Indeed, different mechanisms by which diversity can be maintained in microbial populations have been proposed.

The Ecotype Model, Niche Partitioning and Clonal Interference

The canonical model for microbial species distribution is Cohan's ecotype model. It is based on the periodic selection model, which proposes the following: Mutations with large fitness benefits and recombination are sufficiently rare, such that when they do arise, the mutants have a greater fitness than the resident strains. They will therefore quickly sweep to fixation in the population, eliminating all other existing genotypes. The ecotype model applies this idea to individual niches. It predicts that as species adapt to a given niche, they will compete with other genotypes for the available resources in the niche. In the long-term, the genotype best adapted to the niche will competitively exclude all others and dominate through periodic selection. This would result in a one-genotype to one-niche scenario. In other words, this model proposes that many species co-exist together because the sampled environment contains a large number of available niches.

Of course, genotypes that are excluded through competition with others need not go extinct. Instead, they may evolve to specialize on a different available niche in the same environment. This idea is called "niche partitioning" or "niche differentiation": if many nutrient sources or different spatial areas are available in an environment, different genotypes may coexist, if each requires a unique subset of these nutrients to survive and grow or inhabits a different zone in space. In other words, different genotypes can occupy the available niches in a given environment with minimal competition between them. This can occur more easily if the genotypes are distantly related, since they are more likely to differ in their metabolism and thereby occupy different niches. In contrast, because related strains, which have descended from the same genotype will tend to consume the same resources, competition between them should be particularly strong. They are therefore expected to exhibit "clonal interference": as beneficial mutations arise in multiple cells in the population on a similar time-scale, these lineages of clonal cells compete, eventually resulting in a single lineage dominating the population.

One experiment in which these ideas are interesting to test is Richard Lenski's long-term evolutionary experiment, which began in 1988. In it, 12 replicate populations of *E. coli* have been evolving in a defined minimal medium for over 60,000 generations at the time of writing. In three of the 12 replicate populations, mutants that were fitter than their predecessors arose to fixation in a pattern predicted by models of clonal interference. In the remaining nine populations, multiple genotypes co-existed over large time-scales, spanning more than 10,000 generations. In one population, a mutant arose that could grow on citrate, a carbon source that *E. coli* normally cannot metabolize, thus exploiting an untapped niche in the environment. In some of these nine populations, coexisting strains were found to have evolved to depend on each other (Fig. 1).

Having started from a single clonal population, the long-term evolutionary experiment shows evidence of clonal interference, but also of niche partitioning and niche construction. Some strains evolved to survive in uninhabited niches in the same environment (growth on citrate), while in other lineages new niches were created that could then be occupied by emerging strains. These results, then, are in line with the ecotype model. But can genotypes co-exist in the same niche?

Resource Ratio Theory

Resource ratio theory (RRT), originally proposed by David Tilman in the 1980s, suggests that coexistence under competitive conditions is also possible. The theory considers how one or more competing genotypes may respond to the presence of one or more nutrient sources, and under what conditions two or more genotypes can co-exist stably even if they compete for all available nutrients. What RRT predicts is that such stable coexistence is possible if each genotype is limited by a different nutrient source, and preferentially consumes the nutrient source that limits its own growth rate. Although RRT has not been fully tested in microbes, it is a good candidate to explain microbial diversity in environments consisting of few niches where competitive exclusion may be expected.

Fig. 1 Different models explaining diversity in microbial communities. Each oval represents a niche that is inhabited by bacteria whose genotype is represented by the color of their border, matching their line in the phylogenetic tree above. The ecotype model proposes that each niche will be filled by single genotypes. In cross-feeding, genotypes can survive on metabolites secreted by others. Another possibility is that genotypes migrate into the community and pick up genetic material allowing them to survive in the niche. Finally, RRT suggests that different genotypes can preferentially take up resources in the niche that do not limit coexisting genotypes' growth.

Cross-Feeding and Parasitism

Another idea of how genotypes can coexist is if they depend on each other through cross-feeding, whereby they consume and grow on each other's waste products. It is still somewhat unclear how common cross-feeding is in natural populations. However, it may explain why it is so difficult to culture certain microbial species in the lab (around 1% of environmental isolates): if they depend on others for survival, they will not grow as long as their partners are absent. This principle can be extended to larger communities: if species depend on each other for nutrients, or to adjust environmental conditions, they will cease to eliminate each other and instead converge to fixed frequencies that maintain both types. This can explain the co-occurrence patterns observed in the long-term evolutionary experiments, where newly emerging mutants were able to make use of a niche constructed by the waste-products of the wildtype, thereby cross-feeding off it. Cross-feeding is expected to be even easier to achieve in communities made up of different species, since their metabolic capabilities are more likely to differ and take on complementary roles.

In cross-feeding, one genotype benefits from the otherwise useless secretions of another. Coexistence can also occur if costly molecules secreted by one genotype for its own benefit (within-genotype cooperation), "leak" and simultaneously provide an advantage for others. The non-producing genotype can then be considered to be a parasite, benefiting from a costly molecule produced by another. At an extreme, the non-producing genotype may depend on the other for survival, creating a uni-directional dependence. Such dynamics are described by the Black Queen Hypothesis, which proposes that many genotypes can stably co-exist if one genotype is providing the resources not only for its own type, but also for other neighbouring genotypes that have all lost the ability to produce this resource themselves. Indeed, this has been observed in some natural communities, such as in wild populations of marine bacteria.

Spatial Structure and Biofilms

An important source of different niches is space. Rather than growing in well-mixed liquid cultures as they do in the lab, microbes are typically embedded within dense, sticky aggregates of microbial cells called biofilms. This lifestyle applies to environments ranging from the surface of a leaf to cells growing in mucus in the human gut or lung, or even cells attached to sand particles or forming marine snow in the ocean. Two things change for a cell in a biofilm compared to when it is living in well-mixed liquid: first, it is physically closer to its neighbours, enhancing their effects, and second, if the cell group is large, substrates will not be able to diffuse through the cell mass, leading to differential access to nutrients or toxic compounds depending on a cell's position within the group. Because of these two effects, the position of a cell within these structures and the identity of its neighbours is extremely important for determining its fate in the community.

In addition, if communities are spatially organized, competition between genotypes can be reduced and promote co-existence. Indeed, spatial organisation is a known mechanism by which diversity can be maintained. This is firstly because different genotypes

will only meet and compete at boundaries of their individual patches, and secondly because it provides many niches, allowing each genotype to adapt to the environmental conditions in its local patch. Because we now think that most microbes live in such spatially structured environments, this may be an extremely common mechanism to reduce competition and promote coexistence. Spatial structure can, however, be easily destroyed due to natural phenomena, such as liquid flow or environmental disturbances. In addition, the microbes themselves will tend to migrate in space to find favourable environments or to escape from predators. In many environments, then, competition may increase due to migration or natural environmental disturbances leading to genotypic mixing.

A classic example of how spatial organisation could lead to co-existence comes from another evolutionary experiment using *Pseudomonas fluorescens* in the simple environment of a standing culture. After just three days of growth, the initially clonal population had evolved into three co-existing genotypes. This co-existence depended on spatial structure in the environment and disappeared if the cultures were shaken.

Migration

Finally, diversity can be maintained through frequent migration of genotypes. In most cases, these migrants will not adapt fast enough and will soon be outcompeted in their new habitat. However, one mechanism that may allow for their stable coexistence is horizontal gene transfer, allowing migrants to acquire the necessary genetic material to survive. In such a scenario, the resulting community will be composed of diverse genotypes that all pass through the habitat filter because they have acquired the genes necessary to survive in this habitat. Whether these communities remain stable will then depend on the extent to which the niches of its genotypes overlap, potentially resulting in rising competition. However, if new genotypes continue to migrate into the community, then diversity could be maintained, even if sampled states represent highly transient ones. In support of this idea, genomic data from environmental samples has shown that rather than whole genomes sweeping to fixation, sweeps appear to occur in particular genomic regions independently of the rest of the genome.

The models proposed to explain the maintenance of diversity, then, posit that arising mutants can occupy unused niches, whether they consist of unused nutrients or spatial niches that already exist in the environment. Alternatively, original resident strains may create niches that can then be filled by future mutant strains, leading to co-existence and co-dependence. A third mechanism of co-existence is if the mutants cease to produce the necessary compounds to survive in the environment, but instead rely on the original strains that cooperatively produce these compounds. Although these strains can be considered to be parasitic cheats, they have been shown to co-exist stably with the original strains in a so-called “negative frequency-dependent” manner: Cheats that are very rare can benefit the most, but if they become too common, they can no longer survive and therefore drop in frequency once again.

Taken from the microbial perspective, a gram of soil may contain considerable amounts of space with different niches, each with its own specific conditions, allowing for large microbial populations consisting of hundreds of species to coexist while never even encountering one another. Indeed, a recent study estimated that even though a gram of soil contains more than 10^8 cells of thousands of species, because of spatial organisation at the scale relevant to the microbes, a given focal cell probably only interacts with around 100 others. This would correspond perfectly to the ecotype model. However, models explaining co-existence within niches may still hold true, thereby predicting an even higher genotypic diversity than the number of available niches.

Conclusions

We have come a long way in understanding what Antonie van Leeuwenhoek first saw under his lens. We have uncovered the challenges microbes face in their environment and how they adapt to them. We have established the mechanisms by which microbes evolve and how their genomes are shaped. We have simulated their evolution in very simple conditions and have generated hypotheses as to why microbial populations are so diverse. Despite these developments, we are now at an exciting point in this field, where ecology and evolution are increasingly being integrated. Many open questions still remain: How do species adapt to the presence of competition in their habitat? To what extent do different environments drive genome evolution? Do certain environments favour horizontal gene transfer over others? And to what extent can microbes shape their environment to promote their own survival over others? We already have preliminary answers to these questions, but there still remains much to discover before we properly understand the dynamics of microbial communities as they adapt to one another and their constantly changing environments.

The Social Evolution of Bacterial Quorum Sensing

Jacob Thomas and Stephen P Diggle, Georgia Institute of Technology, Atlanta, GA, United States

Introduction

Quorum sensing (QS) is a form of cell-to-cell signaling in bacteria, which regulates the expression of genes and QS-controlled phenotypes in a population-dependent manner. QS involves the production of small diffusible signaling molecules that are released into the surrounding environment. These are taken up actively or passively by neighboring cells where they have two major consequences. First, the uptake of signal molecules stimulates the production and release of a number of QS-regulated public goods. These goods have a variety of uses, which directly or indirectly influence bacterial fitness. Second, the uptake of signaling molecules stimulates the production of more of the signal itself. This leads to autoinduction, positive feedback at high cell densities (when a quorum is reached), which results in an exponential increase in the production of both signal and public goods. A key function of QS is that it regulates behaviors at high cell densities, when the fitness benefits to producing and responding cells are greatest.

One of the first documented QS systems was described in the early 1970s in the marine bacterium *Vibrio fischeri*, a symbiont of the Hawaiian bobtail squid *Euprymna scolopes*. This species of squid has a ventral light organ which luminesces at night, masking shadows it casts by moonlight and allowing it to evade detection by predators. *V. fischeri* cells colonize the crypts of the squid light organ and produce light. In return, the bacteria get to thrive in a much richer and safer growth environment than the surrounding seawater. *V. fischeri* populations do not luminesce at low population densities, but produce light as a coordinated response to growth at high densities (10^{10} – 10^{11} cells/mL in the light organ), and this is achieved through the production and sensing of QS signals. At low cell densities, signal diffuses away from the producing cell but at high cell densities, it accumulates, binds to an intracellular receptor and activates production of a light-producing luciferase (Fig. 1A). We now know that QS systems are both widespread and diverse, and control a multitude of cooperative behaviors in many bacterial species that aid in growth, motility, biofilm formation, virulence and bacterial warfare.

The Diversity of QS Systems

The first chemical class of QS signaling molecules fully described in Gram-negative bacteria were the *N*-acyl homoserine lactones (AHLs), and these have been particularly well characterized in *Vibrio* spp. and *Pseudomonas aeruginosa*. AHL structure varies depending on the producing species, but all AHLs possess a homoserine lactone ring connected to an acyl side chain of varying length and branch structure (Fig. 1B). As they are amphipathic molecules, they are able to diffuse across cell membranes. When they bind to cognate receptor proteins within a cell, they induce a conformational change that allows the receptor to bind DNA and modulate expression of QS-controlled genes. AHL-bound receptors also increase expression of their own synthase and receptor in a positive feedback loop called autoinduction, allowing for a rapid and coordinated population response to signals (Fig. 1A).

In contrast, Gram-positive bacterial species communicate using signal peptides called autoinducing peptides (AIPs, Fig. 1B). Examples include the competence-sporulation signaling factor (CSF) of *Bacillus subtilis* and the Agr system of *Staphylococcus aureus*. These peptides vary widely in length, sequence and in post-translational modifications and can be linear or cyclic. Signaling peptides are processed during export and the processed form either binds to a membrane receptor or is actively imported and binds a cytoplasmic receiver where they trigger a QS response.

Although AHLs and AIPs are the most extensively studied signaling molecules, bacteria use an array of mechanisms for communication that vary widely in their structures and their mode of delivery. For example, the hydrophobic *Pseudomonas* quinolone signal (PQS), can be packaged into vesicles that aid its dissemination. *Myxococcus xanthus* produces and responds to a surface bound signal in order to coordinate aggregation and differentiation into a multicellular fruiting body. A furanosyl borate diester called autoinducer-2 (AI-2) is secreted by many Gram-positive and Gram-negative species and has been called a ‘universal signaling molecule’ and which we will describe further below (Fig. 1B).

Evolutionary Considerations of Quorum Sensing

Whilst a huge amount of mechanistic understanding has been gained in QS over the last 40 years, relatively little attention has been given to the evolutionary implications of QS. This has changed in the last 10 years. Traditionally it was assumed by microbiologists that QS is selected for because it benefits the local group or population, perhaps by providing individuals with information about diffusivity of the local environment. In contrast, evolutionary theory suggests that cooperative communication is only maintained by selection under fairly restrictive conditions. These conflicting perspectives led to investigations into whether QS in microbes is truly a cooperative behavior.

Fig. 1 QS signaling and examples of QS molecules. (A) The LuxI/R QS circuit of *V. fischeri*. The *N*-acyl homoserine lactone (AHL) synthase LuxI produces AHLs (yellow ovals) which freely diffuse across the cell membrane. At sufficiently high concentrations, they bind the receptor LuxR, which then activates transcription of bioluminescence genes and its own promoter (autoinduction). (B) Examples of QS signaling molecules: (i) N-(3-oxododecanoyl)-L-homoserine lactone (3-oxo-C12-HSL) of the *P. aeruginosa* LasI/R circuit; (ii) N-butanoyl-L-homoserine lactone (C4-HSL) of the *P. aeruginosa* RhII/R circuit; (iii) N-(3-oxohexanoyl)-L-homoserine lactone (3-oxo-C6-HSL) of the *V. fischeri* LuxI/R circuit; (iv) *V. harveyi* autoinducer 2 (AI-2) furanosyl borate ester; (v) Autoinducing peptide 1 (AIP-1) of *S. aureus*, amino acid residues indicated by letters in circles.

A key question for the field of bacterial communication is what defines a signal? This can be largely informed from a large body of evolutionary theory on animal communication. A *signal* can be defined as a behavior (or structure) which elicits a response from a receiver and the signal and response have evolved in the sender and receiver respectively because of that response. Critically, the signal and response must benefit both sender and receiver or the signaling behavior breaks down over evolutionary time. True signals should be distinguished from behaviors that only benefit one party. A *cue* is a feature that elicits a response from a receiver, which evolved because of the benefit to the receiver and does not benefit the sender; a behavior that has been called eavesdropping in a microbial context. Examples of cues in microbes could be metabolic waste products produced by one cell that are then imported and utilized by a receiver. *Coercion* is an activity that evolved in the sender that forces a costly response from the receiver, but that response does not benefit and did not evolve for that purpose in the receiver.

It is not always straightforward to categorize an interaction as a signal, cue or coercion without experimental verification. In the lungs of cystic fibrosis patients, *Burkholderia cenocepacia* responds to AHLs produced by *P. aeruginosa* and upregulates virulence genes. This may be a response to a cue rather than a cooperative signaling interaction, since the benefit to *P. aeruginosa* is unclear. Competent *Streptococcus pneumoniae* cells trigger the fratricide of non-competent kin so they can take up their DNA. It is uncertain whether this is cooperative signaling or an example of coercion by the competent population. With the advent of inexpensive sequencing, incomplete parts of QS pathways are often found in bacterial genomes, calling into question whether they represent true signaling mechanisms. The ‘universal signal molecule’, AI-2, is produced by many different Gram-negative and positive bacterial species, but a response to AI-2 has only been demonstrated in a few examples. Further, AI-2 has been shown to be a product of S-adenosylmethionine metabolism turnover and might, in many cases, simply be a metabolic byproduct that is recognized as a cue (and did not co-evolve in producer and responder). In another example of a disparity between signal producers and corresponding responders, many orphan AHL receptors (LuxR) unaccompanied by their cognate synthase machinery have been cataloged by genome sequencing.

As signal production, and to a greater extent, response to that signal, incurs a fitness cost, differentiating a signal from a cue or coercion allows us to make general predictions about bacterial signaling. First, if the signal has evolved to benefit both sender and receiver, it should usually convey reliable information to be evolutionarily stable. Second, it might be possible for individuals to undermine the reliability of the signal or ‘cheat’ by (i) not producing signal (or engaging in the cooperative behavior controlled by the signal), avoiding the costs of both signaling and cooperation (Fig. 2) (ii) producing increasing amounts of signal without engaging in cooperation, coercing a cooperative response from receivers. How does a quorum sensing population avoid invasion by these cheats and subsequent collapse? Evolutionary theory provides a solution to the problem of how to maintain a reliable signal through the principle of kin selection.

Kin Selection in the Maintenance of Cooperative Signaling

QS and the behaviors it regulates are cooperative and a cooperative behavior by definition benefits the members in a group or population. If a cooperative behavior benefits both the individual performing the action and other individuals, it can be maintained if the *direct fitness benefit*, i.e. the fitness benefit to the producer, outweighs the metabolic cost of the action. When a cooperative

Fig. 2 QS-induction of cooperation and cheating. At low cell densities, green producers produce QS signal (yellow balls) which do not accumulate to high enough concentrations to trigger a response. Gray cheaters avoid the cost of QS signal production. At high cell densities, accumulation of QS signal triggers the production of public goods by producers (blue halos). Cheaters receive the benefit of these public goods (blue arrows) without paying the metabolic cost.

action indirectly benefits another individual at the cost of the actor, this poses a problem since this decreases the fitness of the actor who can then be outcompeted by non-cooperating ‘cheats’.

Kin selection theory proposes a solution to the problem of cheating: if the benefit of cooperation is directed towards a closely-related individual, or kin, this stabilizes the cooperative genes in the population. This is encapsulated in Hamilton’s rule which states that altruism is favored when $rb - c > 0$, where c is the fitness cost to the actor, b is the fitness benefit to the beneficiary and r is their genetic relatedness. When relatedness is high or when the cost of cooperation is low, altruistic behavior can be maintained. Cooperation can therefore provide an *indirect fitness benefit* to individuals that share cooperative genes and the relative importance of direct and indirect fitness benefits will determine whether the cooperative behavior is mutually beneficial or altruistic. A consequence of Hamilton’s rule is that the indirect benefits of cooperation diminishes in populations where the relatedness of its members is low.

In 2001, Brown and Johnstone proposed a kin selection model for the evolutionary stability of QS. They made the assumptions that (1) signals are costly, (2) the cooperative behavior controlled by signaling is costly, (3) the cooperative behavior provides an indirect fitness benefit to group members, and (4) the benefits of both signaling and cooperation increase at high cell densities. They defined an evolutionarily stable strategy as one which, when adopted by the majority of individuals, cannot be displaced or invaded by cheats adopting another strategy. They came to two major conclusions: (1) Cooperation and signaling were both stabilized with increasing cell density. At low cell densities, the costs outweighed the benefits. (2) Cooperation as a strategy was stabilized with increasing relatedness of members, as this increased the indirect fitness benefit of cooperation for the entire population. However, even populations with relatively low levels of relatedness could cooperate to an appreciable level.

Predictions of the Brown and Johnstone model have since been tested experimentally. In 2007, we and others demonstrated that under selective *in vitro* conditions, a QS-controlled protease provides a benefit to *P. aeruginosa* at the population level and that QS signaling is costly to the cell. Cheating signal-blind (defective in the AHL response regulator LasR) or signal non-producer (defective in the AHL synthase LasI) mutants were able to invade a population of wildtype producers. We also found that fitness of cheats was inversely proportionate to their starting frequency in the population and that high relatedness favored the maintenance of QS. *In vivo*, in mouse models of burn and chronic wounds, QS *lasR* mutants were able to invade population of producers even though they were less virulent by themselves than the QS-positive strains. The fitness of these cheats was negatively dependent on their starting frequency in the population, because at low starting frequencies, there are more cooperators for cheats to exploit.

The QS kin selection model made further predictions distinguishing signaling from the signaling-controlled cooperative behavior: unlike cooperation (which is stabilized monotonically with increasing relatedness) the stability of signaling increases with relatedness up to a point and then decreases, reaching a maximum at intermediate relatedness. The authors proposed that at high relatedness, kin selection favors cooperation and an inexpensive signal will suffice. At low relatedness, cooperation is not selected for, and so there is no selection for signaling. At intermediate relatedness however, there is selection for cooperation but the population is vulnerable to cheating. This was predicted to promote higher levels of signaling to force individuals to cooperate but at the same time, selection forces cheaters to ignore higher and higher levels of signal (competitive devaluation of signal). A later theoretical study proposed that this last prediction only holds true if the cost of cooperation is low and only a few cooperating members are required to bring the benefit of cooperation to the entire group. When Popat and coworkers explicitly tested this prediction in *P. aeruginosa*, they confirmed that at low relatedness, both signaling and cooperation broke down as the population was invaded by cheats. This occurred through a variety of mutations in both signaling and response pathways. However, they did not observe maximal selection for signaling at intermediate relatedness. Instead, they found that the stability of signaling monotonically decreased with decreasing relatedness. They suggested that this was because the initial model assumed cooperation and signaling to evolve independently, but autoinduction provides positive regulatory coupling between the two processes, limiting the rapid evolution of coercive high-signal low-cooperation mutants.

Strategies to Promote Kin Selection

In order for kin selection to be an effective stabilizing force on cooperation, cooperators must solve the problem of directing cooperative benefits primarily to kin and not to competitors. This can occur in different ways, both passive and active.

Segregation

Hamilton described one solution in the form of limited mixing or population viscosity. Applied to a microbial context, when individuals reproduce asexually, local areas are likely to be colonized by one clone (relatedness: $r = 1$) and if cooperators indiscriminately distribute public goods to neighbors, those neighbors are likely to be highly related and the indirect fitness benefits will be high. Conditions of high assortment (low mixing) are also favored in structured spatial environments and in bacterial biofilms. Darch and coworkers showed that *Pseudomonas aeruginosa* formed primarily clonal aggregates in an environment that simulated the sputum of a cystic fibrosis lung and that QS signaling and therefore QS-controlled cooperation was largely confined within aggregates. In *V. cholerae* and *P. aeruginosa* biofilms, the structural properties of extracellular matrix exclude invading non-cooperators, making the matrix a relatively non-cheatable public good.

Segregation can also be achieved by direct antagonism. Many Gram-negative bacteria use a type six secretion system that penetrates the cell wall and directly injects toxins into neighbors. In *Vibrio cholerae* and *Burkholderia thailandensis*, this system can be QS-controlled and fires at high cell densities. This has the effect of segregating populations that would otherwise be mixed into clonal patches and modeling and genomic analysis shows that this can promote the evolution of cooperative behaviors. *V. fischeri* strains use this strategy to eliminate competing strains in crypts of squid light organs. Bacteria possess a diverse arsenal of antagonistic strategies including contact-dependent growth inhibition (Cdi) systems and diffusible bacteriocins, all of which in theory would work to segregate populations.

Kin Discrimination

Another strategy for stabilizing cooperation via kin selection works by identifying related individuals and preferentially directing the benefits of cooperative actions toward them, a term called *kin discrimination*. *Myxococcus xanthus* preferentially cooperates with related individuals to form multicellular fruiting bodies by recognizing a polymorphic surface protein TraA. In *Staphylococcus aureus*, QS autoinducing peptides and their receptors are classified into four known kin recognition groups; the AIP of one group can block the receptors of other groups, preventing expression of virulence genes and limiting the ability of potential non-cooperators from establishing an infection.

Repression of Competition

Signaling and cooperation in bacteria can also be stabilized by coupling it to another process required for bacterial fitness. If the opportunities for cheating come with large fitness costs, individuals can be constrained to only increase their fitness by contributing to the productivity of the entire group. This removes the opportunity for cheating and selects for increased cooperation. One study reported that control of a type VI secretion system in *B. thailandensis* by QS led to targeting and killing of QS-cheats in co-culture on solid surfaces, an example of *policing*. In *P. aeruginosa*, QS controls the production of hydrogen cyanide, a cooperative behavior that can inhibit competition by other species and aid in virulence. QS mutants become sensitized to cyanide and so their growth is inhibited in a population of cooperators. *Pleiotropy*, the ability of a single gene to affect multiple phenotypes can also be used as a tool to repress competition. In *P. aeruginosa*, quorum sensing controls expression of the cytoplasmic nucleoside hydrolase, a private good that allows use of adenosine as a carbon source. When adenosine is present in the environment, cheats that are defective in QS cannot utilize it as a carbon source and pay a fitness cost.

It should be noted that strategies for stabilizing cooperation are not exclusive, often overlap, and are sometimes ambiguous to interpret. For example, in *B. thailandensis*, type VI secretion could act both as a mode of policing and as a method for spatial structuring that aids in kin selection.

Complexities of QS

The majority of QS studies have been performed *in vitro*, where cells are allowed to grow to high densities in batch conditions. In these conditions, QS provides a greater benefit at higher densities because QS controlled public goods are more efficiently utilized. However, what constitutes a quorum and to what extent quorum sensing occurs in natural environments are important considerations that have been largely ignored. Local rates of mass transfer and QS signal degradation by both biological and abiotic factors determine the amounts of signal available to a population; a single cell can respond to its own QS signal if mass transfer is sufficiently low and signal stability is high. Redfield proposed that individual bacteria primarily used signaling molecules to determine the local diffusion rate to decide whether to produce costly extracellular factors, a term called 'diffusion sensing'. In this study, she argued that population level selection had not been experimentally demonstrated and that bacterial signaling is an

individual trait, subject only to individual selection and is misinterpreted as a social behavior. However, cheating, a consequence of sociality, has since been documented in a number of studies in both *in vitro* and *in vivo*. We and others have proposed that the two terms are not mutually incompatible; the local rate of diffusion and mass transfer is an important environmental variable that greatly affects both the direct and general fitness benefit of a secreted product. Many bacteria including *Pseudomonas* and *Vibrio* spp. simultaneously use two or more QS signals, to solve the problem of distinguishing environmental from social information. *P. aeruginosa* integrates signals from two AHLs, the more stable C4-HSL and the less stable 3-oxo-C12-HSL, to tailor exofactor secretion in response to cell density and local mass transfer rates. Recent studies have shown that these connected AHL-responsive circuits can be uncoupled both in clinical strains and *in-vitro* evolved populations, allowing *P. aeruginosa* some plasticity in QS control of behaviors.

The Future of QS Research

The majority of studies that have moved our understanding of QS forward, have taken place *in vitro*, in growth conditions not intended to mimic the natural environment. *In vitro* experiments are often designed to exaggerate a selective condition, in order to more easily identify social behaviors and test the predictions of evolutionary theory. While this approach has been extremely useful in building a foundation of fundamental research, we have much to learn about microbial communication and sociality in natural settings. Complex microbial communities can involve many interacting species and are impacted by spatial structuring, ecological settings and host interactions. Progress is being made in increasingly sophisticated experiments that add these layers of complexity to *in vitro* conditions as well as in deciphering the behavior of communities using genomic and transcriptomic approaches. As researchers improve upon and continue to apply the fundamental principles of sociomicrobiology to living systems, this will advance our knowledge of communities in natural and clinical systems in ways that may greatly impact applications for human health, industry and the environment.

Glossary

Apicoplast A plastid-like organelle just anterior to the nucleus delimited by four membranes and containing its own genome. Named for its ubiquitous presence in Apicomplexa.

bradyzoite The slowly dividing, infectious, asexual stage found within tissue cysts in the intermediate host. From the Greek for 'slow' (*brady*) 'little animal' (*zoite*).

endodyogeny Process by which tachyzoites and bradyzoites divide involving creation of two daughter cells wholly within a mother cell. From the Greek for 'gives rise to two' (*dyogeny*) 'inside' (*endo*).

micronemes Small, thin, anterior organelles that secrete their contents onto the parasite's surface at the start of the invasion process. From the Greek for 'small' (*micro*) 'thread' (*nema*).

micropore A small, single invagination anterior to the nucleus with an apparent clathrin coat presumed but not yet demonstrated to be involved in endocytosis.

oocyst The mature, environmentally robust product of the sexual cycle shed in its immature form in cat feces and comprising a cyst wall and two sporocysts, each of which contains four sporozoites.

paralogous The state of being derived from the same ancestral gene.

rhoptries Club-shaped, apical organelles that release their contents into the nascent parasitophorous vacuole. From the Greek for 'club' (*rhoptry*).

sporozoite The product of the sexual cycle, found as two sets of four within the oocyst.

tachyzoite The rapidly dividing, asexual stage. From the Greek for 'fast' (*tachy*) little animal (*zoite*).

tissue cyst The protective structure containing the asexual bradyzoites in the intermediate host. Also known as the pseudocyst.

zoonosis A disease of humans that derives from a reservoir of nonhuman animal infection. From the Greek for 'disease' (*nosos*) originating from 'animals' (*zoo*).

Abbreviations

DHFR	dihydrofolate reductase
GAG	glycosaminoglycan
GRA	dense granule protein
HXGPRTase	hypoxanthine/xanthine/guanine phosphoribosyl transferase
IFN	interferon
IL12	interleukin 12
IPN	intraparasitophorous vacuolar network
MIC	microneme protein
PVM	parasitophorous vacuole membrane
RFLP	restriction-fragment-length-polymorphism
RON	rhoptry neck protein
ROP	rhoptry protein
STAT	signal transducers and activators of transcription
TRAP	thrombospondin-related anonymous protein
UPRTase	uracil phosphoribosyl transferase

Defining Statement

Toxoplasma is an obligate, intracellular parasite that causes a range of symptoms in its exceptionally broad host range.

[☆]*Change History*: September 2014. JC Boothroyd introduced small edits in the text of the article including citations, added the sections 'Applications' and 'References', and added Figures

This article is an update of J.C. Boothroyd, Toxoplasmosis, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 732–743.

Introduction

Toxoplasmosis is caused by the protozoan *Toxoplasma gondii*, an obligate, intracellular microbe whose definitive host is the family Felidae (cats). *T. gondii* has an exceptionally broad range of intermediate hosts, including humans, in which the asexual cycle can occur resulting in serious disease. It is found throughout the world and, in terms of the number and range of hosts infected, *Toxoplasma* may be the most common protozoan infectious agent of warm-blooded animals.

The genus *Toxoplasma* falls within the phylum Apicomplexa and is a close relative of the nonhuman pathogens, *Neospora* and *Sarcocystis*. It is more distantly related to *Eimeria*, the causative agent of coccidiosis in birds and more distant still to *Plasmodium* and *Cryptosporidium*, the etiologic agents of malaria and cryptosporidiosis, respectively. At the still more distant level, *Toxoplasma* is also related to free-living dinoflagellates but the evolutionary timescales involved are enormous (e.g., humans and flies are relatively close cousins by comparison).

Infection of healthy humans by *Toxoplasma* is usually of little consequence but human disease will often occur in either of two scenarios: in the child of a woman infected for the first time during pregnancy and in individuals who are immunocompromised. Occasionally, however, serious eye infections can occur even in people who are otherwise healthy. This unusual occurrence may be the result of an unusually large inoculum, the particular genetic makeup of the person infected or, perhaps, the strain of parasite responsible for the infection.

In animals, toxoplasmosis is also generally self-limiting with the most serious consequences (abortion) being from acute infection during pregnancy. This is a particularly serious problem in the raising of sheep.

The relative ease of handling this haploid agent in the laboratory and the wide range of natural hosts have made *T. gondii* a popular model for experimental study of intracellular infection. Through such studies, much has been learned about the way in which this common microbe interacts with its host, about its population biology, and about the molecular details behind its obligate intracellular life style.

Classification

T. gondii is a protozoan within the phylum Apicomplexa, Class Conoidasida, order Eucoccidiorida, suborder Eimeriorina, family Sarcocystidae. The genus name derives from the Greek word *toxos* meaning bow and *plasma* meaning form and refers to the bow-shaped tachyzoite. The species name derives from the name of the North African rodent from which the parasite was first isolated in 1908 by Nicolle and Manceaux. It was simultaneously described by Splendore in Brazilian rabbits.

Life Cycle

The complete life cycle of *T. gondii* was not established until about 1970 when four groups independently identified the cat as the definitive host, meaning this is the host in which *Toxoplasma* enters into its sexual cycle. Figure 1 depicts the complete life cycle as consisting of two, potentially independent cycles, one asexual and the other sexual. This has been done in order to emphasize that, at least on paper, the parasite appears fully capable of propagating itself through either cycle. The degree to which these two cycles intermix (arrows 4 and 8) is not known. In practical terms, this uncertainty means that it is not clear what fraction of infection in the

Figure 1 The life cycles of *Toxoplasma gondii*. The asexual cycle can occur in a large number of warm-blooded animals and is shown on the left. It involves an equilibrium between the rapidly dividing tachyzoite ('tachy' means fast in Greek) and the more slowly dividing bradyzoite (arrows 2 and 3; 'brady' means slow in Greek). Transmission in the asexual cycle is through the ingestion (carnivorism) of meat and other tissue containing the infectious encysted bradyzoites (arrow 1; e.g., rat to pig or pig to human). Scavenging allows the parasite to cycle back down the food chain (e.g., pig to rat). The sexual cycle is shown on the right and involves schizogony, gametogenesis, fertilization and development into oocysts (arrows 5, 6, and 7) in the gut epithelium of felines. Cat-to-cat transmission through the sexual cycle is theoretically possible by ingestion of oocysts in fecal contamination (arrow 10). Crossover between the two cycles is represented by arrows 4 and 8, but the extent of this in nature is not known.

intermediate host (e.g., humans) is a result of ingesting meat containing tissue cysts (arrow 1) versus accidental ingestion of oocysts in the environment (arrow 8).

The tachyzoite stage is by far the best studied, mainly because it is easy to grow this form *in vitro*. The other asexual stage, the slow-growing, encysted bradyzoite is poorly understood. Fortunately, however, protocols have recently been developed that can cause tachyzoites to efficiently differentiate to the bradyzoite stage *in vitro*. These protocols rely on a number of stresses (certain drugs, heat, pH) that stimulate the differentiation pathway. Although the differentiation *in vitro* may not be complete, the availability of these protocols has opened up the way for more detailed studies of this critically important stage, which previously could only be obtained in small amounts from the tissue of infected animals.

The two asexual stages are similar in overall morphology with mostly the same complement of organelles. The major differences are in the presence of many amylopectin granules in the bradyzoite and a cyst wall that encloses the entire complement of bradyzoites in any given vacuole. The metabolic differences are not clear, although the existence of stage-specific isoforms of some glycolytic enzymes (e.g., enolase and lactate dehydrogenase) suggests the possibility of a fundamental difference in sugar metabolism. Such differences might be related to the presence of the amylopectin granules and/or the polysaccharide-containing cyst wall.

The sexual stages have only been described morphologically in the gut of infected cats (it has not yet been possible to grow any of these stages *in vitro*). The process of gametogenesis, which occurs in the epithelium of the small intestine, conforms to classic coccidian rules including schizogony where a multinucleated state is reached followed by segmentation to yield multiple uninucleated merozoites. Mating between micro- and macrogametes has never been directly observed but is presumed to occur within infected epithelial cells. The process results in a zygote, which then encysts yielding an immature oocyst. This is released into the environment where, after approximately 2-days of exposure to air, it develops into a mature, infectious oocyst comprising two sporocysts, each with four sporozoites. The genetic relationship of the eight sporozoites within a single oocyst has not yet been determined; that is it is not known when the three divisions occur to take the oocyst from one to eight organisms and which of those divisions are mitotic vs. meiotic.

Clinical Aspects and Public Health

Symptoms

Toxoplasma causes disease in humans primarily under two circumstances: the developing fetus of a woman who acquires her first infection during pregnancy and persons who are immunocompromised. The disease that results varies from mild to severe and sometimes fatal. Note, however, that in persons who are infected *in utero* the disease may not appear until many years later, when the individual is in the second decade of life or older.

The prevalence of seropositive adults ranges from approximately 5% to 20% in the United States to as high as 50–85% in France and many developing countries. Historically, severe disease has not been common because of the low number of persons who fall within the two disease-susceptible groups mentioned above: the children of acutely infected pregnant women and people who are immunocompromised. The AIDS epidemic obviously produced a huge increase in the number of people in the immunocompromised category. Initial results indicated that, if left untreated, about one-fourth of AIDS patients who harbored a chronic infection of *Toxoplasma* (most cases of toxoplasmosis in AIDS patients are thought to be due to reactivation of historic, quiescent infections) were liable to develop the potentially fatal condition of toxoplasmic encephalitis. Within the United States, this proportion has dropped in the last decade, probably as a result of three factors. (1) Improved anti-HIV therapies (with a resulting improvement in general immune competence). (2) Prophylactic treatment with trimethoprim/sulfamethoxazole for another opportunistic infection, *Pneumocystis*: such treatment may have the added benefit of controlling *Toxoplasma* infection, if present. (3) Deliberate prophylaxis for *Toxoplasma* in patients who are seropositive and whose CD4 T-cell counts are low. Data on toxoplasmosis in AIDS patients in the developing world are scant but it appears that toxoplasmic encephalitis may be a significant problem in the AIDS populations of those countries just as it was in the United States prior to the aggressive treatment protocols that are in place today.

Congenital infection rates vary by country, in proportion to the seropositivity of the adult population; in the United States, there are no exact numbers but current estimates are that approximately 400–4000 congenitally infected children are born each year. The probability of transmission from an acutely infected mother to the developing fetus varies with the stage of the pregnancy: acute infections in the first trimester are the least likely to be transmitted, whereas third trimester infections are the most likely to be transmitted. As for many congenital diseases, however, the outcome is worse when the infection occurs earlier in the pregnancy: first trimester infections can lead to severe neurological disease (blindness and retardation) or even death, whereas third trimester infections are more mild and may even yield no symptoms at birth. This is not to say that no disease will occur in this latter group: it appears that the parasite can lie essentially dormant and erupt in early adulthood leading to various symptoms, most notably sudden blindness in one eye due to severe retinal destruction. Drug treatment of acutely infected pregnant women can reduce the probability of congenital transmission but, as discussed below, such treatment is not without significant risk to the fetus.

Diagnosis

Serology is the most common method for diagnosing infection with *Toxoplasma*. Acute infection in pregnant women is usually diagnosed from a high IgM or IgA antibody titer and/or a rise in IgG in successive serological samples taken at multiweek intervals

during the pregnancy. Antibody avidity is also used to discriminate between an acute and chronic infection. In countries like France where the incidence is high, strict monitoring is in place: women are tested for anti-*Toxoplasma* titers at the time of marriage and those who are seronegative and later become pregnant are monitored repeatedly for signs of seroconversion (equating to an acute infection). If an acute infection is detected, it is now possible to monitor for transplacental transmission to the fetus (which is the real concern) by amniocentesis and polymerase chain reaction to detect the parasite (or, rather, its deoxyribo nucleic acid (DNA)) directly.

Treatment

Current treatment of acute infection in nonpregnant humans relies on the synergistic action of pyrimethamine plus sulfadiazine, which combine to block folate metabolism through inhibition of dihydrofolate reductase (DHFR) and dihydropteroate synthase, respectively. Unfortunately, even this powerful combination has little effect on the chronic form of the parasite (the bradyzoite), and thus treatment does not completely eliminate the infection. As a result, in immunocompromised individuals the drug therapy must be maintained for long periods to prevent recrudescence of the infection. This is not a simple option as sulfadiazine is poorly tolerated by many patients and its use often must be stopped due to side-effects. Other therapies, while showing some promise, have yet to prove as effective as pyrimethamine plus sulfadiazine (e.g., pyrimethamine plus clindamycin and the newer drug, atovaquone), although better formulations and treatment protocols could dramatically improve their efficacy.

Because of drug toxicity, treatment of pregnant women is always a clinically complicated decision. In countries like France, which have the most experience of managing such patients, acute infection in the mother is treated with spiramycin although the benefit of such treatment is not firmly established. If transmission to the fetus has been demonstrated, then the more potent but more toxic combination of pyrimethamine plus sulfadiazine is used because the risk of serious disease outweighs the possible harmful effects of the drugs. Therapeutic abortion is also sometimes chosen.

Public Health

In the absence of a vaccine and given the short-comings of the drugs mentioned above, the best approach to controlling human toxoplasmosis is avoidance. This is easier said than done, however, as evidenced by the fact that infection with this parasite is so prevalent worldwide.

Meat-eaters are especially at-risk from undercooked lamb and pork, although the latter may not be a major source because of centuries of knowledge that severe disease can result from eating undercooked pork and the resulting common knowledge to avoid consuming such meat. Lamb, on the other hand, is frequently eaten extremely rare in many cultures. (Note that beef, while also often eaten rare or raw, is not such a problem because, for unknown reasons, bovines appear to harbor fewer numbers of tissue cysts in their muscle or other tissue.) It is thus critical that persons at-risk, for example, persons who are immunocompromised and seronegative women who might become pregnant, avoid eating meat that is not thoroughly cooked. Fortunately, freezing also kills tissue cysts and thus this simple preventative measure can also be used to reduce the risk of infection.

Toxoplasma's unusual life cycle means that simple vegetarianism will not enable someone to avoid infection. The oocysts shed by cats are extremely stable in the environment and cats are particularly fond of defecating in loose soil such as that found in vegetable gardens. It is thus fairly simple for vegetables to be contaminated with minute amounts of oocysts and so at-risk persons should take special care to eat only cooked or thoroughly washed fresh vegetables.

Finally, the stability of the oocysts also means that they can be ingested through daily activities as innocuous as gardening or playing in a dusty field or sandbox. Obviously, cleaning a pet cat's litter tray is not appropriate for at-risk persons although because oocysts take approximately 48 h to become infectious after shedding, regular daily removal of the feces can reduce the risk of infection. Even better, keeping cats strictly indoors and feeding them only on tinned or dried foods can virtually eliminate the chance of their acquiring an infection.

One of the key deficiencies in our understanding of toxoplasmosis is what fraction of human infection comes from ingestion of tissue cysts in undercooked meat products versus oocysts in environmental contamination. This point is discussed further below.

Molecular Biology and Genetics

Genome and Gene Expression

Except for the diploid zygote, all stages of *Toxoplasma* are haploid with a genome of approximately 6.5×10^7 bp per nucleus. Using a combination of physical and genetic means, it has been shown that *Toxoplasma* has 14 chromosomes in its nucleus. The genomic sequences for Type I, II, and III strains have been essentially completed, as have now over 60 additional strains. These genome sequences are all available at www.toxodb.org/toxo/. This is an extraordinary advance and has opened up many new areas of investigation. Unlike some other parasitic protozoa, gene expression in *Toxoplasma* appears to be similar to that seen in other model eukaryotes such as yeast or humans. For better or worse, this has allowed investigators to focus on the coding function of the genes rather than any subtleties about how they are regulated.

In addition to the nuclear DNA, two other genomes are present in *Toxoplasma*: the approximately 35 kb genome of the plastid-like structure known as the apicoplast (see below) and as yet incompletely characterized mitochondrial DNA.

Genetics

Because of its haploid nuclear genome, it is relatively easy to select phenotypic mutants in *Toxoplasma*. A large number of such mutants have been described including lines that are temperature-sensitive for growth, deficient in development, disrupted in cell cycle, or resistant to one or more drugs. Mutant libraries have been made using chemicals or random insertion of DNA sequences carrying selectable markers. The latter has also been done with plasmids carrying a unique sequence that serves as a 'signature' or bar code allowing pools of mutants to be analyzed as a group.

Such mutants have been used as an unbiased way to identify important genes, either through genetic mapping, complementation or sequencing. The latter is an especially exciting development because of 'next generation' sequencing which allows the entire genome of multiple mutants to be analyzed in a single day, thereby revealing mutations responsible for mutant phenotypes. This promises to be a highly productive approach to dissecting key functions in *Toxoplasma* in the near future and has already yielded interesting results on DOC2, a protein involved in membrane fusion, and CDPK3, a calcium-dependent protein kinase involved in signaling related to invasion and egress.

Molecular Genetic Tools Available for the Study of *Toxoplasma*

In the past decade or so, there has been a substantial effort invested into the development of molecular genetic techniques for the study and manipulation of *Toxoplasma*. The large number of such techniques now available makes *Toxoplasma* one of the most easily studied and 'engineered' of any protozoan parasite.

Initially, transient expression of suitably engineered DNA plasmids was achieved using electroporation. There are now several selectable markers reported for stable transformation of *Toxoplasma*: bacterial chloramphenicol acetyl transferase (conferring resistance to chloramphenicol); pyrimethamine-resistant DHFR; bacterial tryptophan synthase (*trpB*, conferring tryptophan prototrophy); bacterial *ble*, conferring bleomycin and phleomycin resistance; bacterial β -galactosidase (*lacZ*); jellyfish green fluorescent protein and, in the appropriate null backgrounds, *Toxoplasma* hypoxanthine/xanthine/guanine phosphoribosyl transferase (HXGPRTase); and uracil phosphoribosyl transferase (UPRTase). All have been successfully used to introduce exogenous or engineered genes into the parasite for expression.

This large collection of selectable markers has made reverse genetics a staple of the *Toxoplasma* field. Many genes have been specifically disrupted through targeted insertion/deletion using one or other of the selectable markers listed above. This has allowed the function of many loci to be investigated. Of course, essential genes in a haploid organism cannot be deleted, by definition, unless a backup copy is provided. This has been done using the popular tetracycline-regulated expression system that allows the backup copy to be specifically turned on or off by adding/subtracting the drug, as well as more recent methods involving destabilization domains fused to proteins of interest and methods using engineered forms of Cre recombinase.

Tachyzoites engineered to inject Cre recombinase have also been developed and used to probe 'Cre reporter' mice where the presence of injected Cre turns on a fluorescent marker like green fluorescent protein (GFP). This has allowed infected cells to be readily identified *in vitro* and, more interestingly, has revealed that many cells that have received the injected Cre are not infected. *In vitro* such cells include some that appear to have never been infected, suggesting that the parasites can inject into cells they do not then invade. Whether such is a chance, abortive invasion event or a selected trait that enables the parasite to co-opt cells it has no intention of infecting is not yet clear. Strikingly, such uninfected/injected cells are also seen *in vivo* but there it is not possible to say if such are cells that were infected and the invading parasite was subsequently cleared or if they are cells that were injected into but never invaded. The implications of such cells for the overall interaction of *Toxoplasma* with its host, especially neurons in the brains of chronically infected animals, could be profound.

Cell Biology

Organelles

As an obligate, intracellular parasite, *Toxoplasma* has many specialized organelles dedicated to this lifestyle. Some of these are shown in Figure 2 and each will now be briefly described.

Apicoplast: This is a spherical, plastid-like organelle just anterior to the nucleus. Its importance to *Toxoplasma* and related parasites is evident from the fact that it is found in Apicomplexan parasites ranging from *Toxoplasma* to *Eimeria* and *Plasmodium*. Its existence has been known for decades, going by various names (e.g., Golgi adjunct, and spherical body). It is delimited by four membranes and contains its own genome whose sequence revealed its relatedness to plastids of algae. The data further argue that it was acquired by the ancestor of *Toxoplasma* (and other Apicomplexa) through a secondary endosymbiosis of an algal-like eukaryote. The function of this organelle is not entirely known and its small genome has provided few clues. A thorough study, however, of the proteins encoded in the nucleus that ultimately are targeted to the apicoplast argue that it has an important role in fatty acid metabolism among other functions. As mentioned below, its conservation throughout the Apicomplexa and the complete lack of a similar organelle in the animal hosts of *Toxoplasma* make it an extremely attractive drug target. Already, one drug that had been empirically determined to be very effective against Apicomplexan parasites, clindamycin, has been shown to act through interfering with translation in the apicoplast. It is likely that this organelle will provide rich pickings for future drug-discovery programs.

Figure 2 Ultrastructure and morphology of the tachyzoite. This schematic shows a cut-away of the tachyzoite stage of the parasite. The overall morphology is very similar for the bradyzoite and sporozoite. Note that the microtubules gently spiral down the body, starting from the anterior polar ring and ending about two-thirds along the length of the parasite. This is why they have an oval appearance in the cross-section shown.

Dense granules: These are small, spherical, secretory organelles distributed throughout the tachyzoite. They release their contents ('GRAs') into the parasitophorous vacuole upon invasion into a host cell and are believed to help modify the vacuole to make it better suited for growth of the parasites within. One of the most abundant constituents of these granules is a potent NTPase that may have a role in scavenging nucleosides from the host cell although this has yet to be directly demonstrated. At least one dense granule protein, GRA7, is present on the surface of the infected host cell although its function there is unknown. GRAs can also somehow cross the parasitophorous vacuole membrane (PVM) and interact directly with cytosolic and nuclear components of the host cell, as discussed further below.

Inner-membrane complex: This is a set of collapsed vesicles almost completely enveloping the parasite and closely apposed to the parasite's plasma membrane. Together with the latter, they make the parasite surface appear as if it consists of a triple layer of membranes. It is one of the first organelles to appear *de novo* during endodyogeny and behaves as if it were the nucleating point for formation of the two daughter parasites. The inner-membrane complex likely plays many roles, including an anchor for some of the machinery involved in 'gliding motility' of the parasite. Many components of the inner-membrane complex have been identified and shown to play key roles in endodyogeny and invasion.

Micronemes: These are numerous, thin, anterior organelles that secrete their contents ('MICs') onto the parasite's surface at the start of the invasion process. Their components appear key to motility and invasion. One microneme protein, MIC2, has been directly implicated as a way that the parasite attaches to an exterior substrate like a host cell and then pulls itself in. Another, AMA1 (the *Toxoplasma* orthologue of Apical Membrane Antigen 1 first identified in *Plasmodium*), has been found at the so-called 'moving junction' that forms as the parasite enters a host cell (see the section on 'invasion', below). This moving junction is a ring-shaped entity that represents the point of contact between the parasite and host cell surfaces as the parasite invades into the nascent parasitophorous vacuole. The moving junction also comprises several proteins from another secretory compartment, the rhoptries, as discussed next.

Rhoptries: These are club-shaped, apical organelles that release their contents early in the invasion process. The functions of their protein contents are just beginning to be understood and it is looking like they play several crucial roles in the parasite's interaction with the host. First, as just mentioned, the rhoptries release proteins that collaborate with AMA1 to form the moving junction. Interestingly, these rhoptry proteins all emanate from the more apical, neck-like region of the organelles, rather than the bulbous base. On the basis of this Rhoptry Neck origin, they have been designated 'RON' proteins. It appears that some RONs interact with the host cytoskeleton while at least one, RON2, protrudes out of the host cell where it can be bound by the transmembrane AMA1 embedded in the parasite surface. This interaction likely represents the means by which the parasite and host plasma membranes are maintained in such close apposition at the moving junction. Tachyzoites rely on one RON2/AMA1 pairing while sporozoites use a paralogous pair known as sporoRON2/sporoAMA1. This latter pair are encoded by distinct but paralogous genes that are turned on specifically as sporozoites develop in the oocyst. Interestingly, recent results suggest the moving junction can form without AMA1 being present indicating that the picture at the moving junction is more complex than currently understood.

Rhoptry bulb proteins ('ROPs') also appear to be injected into the host cell during invasion. Some ROP proteins are found associated with the parasitophorous vacuole membrane (PVM), some are found associated with the intravacuolar network while others are found within the host nuclei! The best studied of the ROPs are key 'effectors' that influence the interaction of the parasite with the host cell and are discussed further below.

Micropore This small, single invagination anterior to the nucleus has an apparent clathrin coat and is presumed but not yet demonstrated to be involved in endocytosis.

Acidocalcisomes These are small, membrane-limited vesicles that can be difficult to visualize but that appear to play an important role in maintaining calcium homeostasis. They are rich in polyphosphates and, as the name implies, they are acidic compartments that use proton pumps to maintain their pH.

The Lytic Cycle

Toxoplasma is an obligate intracellular parasite. As such, and given that it causes lysis of the host cell after going through several rounds of replication, the classic virology term, 'lytic cycle' is perfectly suited to describing the various stages of intracellular growth. The cycle begins with attachment followed by invasion, replication (including vacuolar modification), and egress (Figure 3).

Attachment

Taking all the data together, the most likely model for attachment involves at least two steps. First, a resident surface molecule, perhaps one or more of the glycolipid-anchored surface antigens, may interact with as yet unidentified host ligands. This part of the model is based on studies showing that antibodies to the major surface antigen, P30 or SAG1, can block binding of parasites to host cells (fixed or live) and thus prevent invasion. The putative ligand on the host cell side is likely to be something that is nearly ubiquitous as *Toxoplasma* is remarkable for its ability to invade almost any vertebrate cell it encounters, at least *in vitro*.

Following such initial interactions, a signal is sent which results in release of additional molecules involved in invasion, including the micronemal MIC2 and AMA1 proteins, mentioned above. MIC2 is a homologue of the better studied 'thrombospondin-related anonymous protein' (TRAP) molecule of *Plasmodium* sp. TRAP and MIC2 have domains whose sequence suggests an ability to bind glycosaminoglycans (GAGs). GAGs and other proteoglycans have been implicated as key ligands on the host side.

Electrophysiological studies have provided further insight into this initial attachment stage. They show that there is a brief, transient spike of conductance across the host cell plasma membrane suggesting that there is a profound perturbation of the integrity of the host cell plasma membrane associated with the initial attachment. The significance and role of this event are not yet known, although it is tempting to speculate that it somehow is connected to the process of introducing ROP proteins into the host cell; the perturbation seems too brief to reflect the introduction itself but it could be related to the process that does this.

Invasion

Invasion is an active process involving many parasite functions and is accompanied by the sequential discharge of several distinct intracellular compartments including the micronemes, rhoptries, and dense granules. The contents of these compartments serve many functions. Among these, it is presumed that some number of molecules facilitate the invasion process itself, perhaps providing the link between the host cell surface and the parasite's actin/myosin-based motors that provide the driving force of invasion. Thus, molecules such as MIC2 or AMA1 might enable the parasite to literally pull itself into the host cell, creating the moving junction described above and a nascent parasitophorous vacuole as it proceeds. Physiology studies have clearly demonstrated that the PVM is largely derived

Figure 3 The lytic cycle of asexual reproduction. In this cartoon, the stages of attachment, invasion, replication, and egress are shown. Note that the host cell may have multiple vacuoles. Egress is shown here as involving both membrane destruction and active egress through semi-intact membranes. This is the least well-studied part of the lytic cycle.

from the host cell's plasma membrane. Lipid-labeling studies have shown that subsequent elaboration of the PVM and intravacuolar network also involves 'theft' of host membranes, likely endoplasmic reticulum for the most part.

Replication

The first challenge to the intracellular parasite is to create the necessary niche for optimal growth. For *Toxoplasma*, this requires modifying the vacuole created on invasion. The PVM appears largely devoid of host markers suggesting that during its formation, most resident proteins are removed from the invaginating host plasma membrane through some sort of molecular sieve that must exist at the circular moving junction that migrates down the parasite surface creating the PVM in its wake. Very quickly, however, parasite proteins, particularly the ROPs, begin to be detectable on the PVM. Few host proteins are ever detected, suggesting that no fusion with lysosomes or other compartments of the host endocytic pathway occurs. This is consistent with ultrastructure studies on infected cells and the fact that there is no acidification of the vacuole.

The major features of the PVM are as follows:

1. Pores arise in the PVM that are permeable to molecules of up to about 1300 Da without regard to charge. These structures, which have yet to be seen and are of unknown composition, are presumed necessary to allow the parasite to feed freely on host cell nutrients. They also result in the lack of a physiological barrier between the vacuolar space and the host cell cytosol. Thus aspects like pH, osmolarity, concentration of specific ions, and so on, should be similar if not identical between these two compartments.
2. An extensive intravacuolar network forms inside the parasitophorous vacuole (PV). This is a loose meshwork of tubules of unknown composition and function. The IPN has been reported to be continuous with the PVM suggesting it may be used to increase the effective surface area of the PVM, although there are no data to show that this is physiologically the case. It is rich with dense granule proteins.
3. Host cell organelles such as mitochondria and endoplasmic reticulum are recruited around the PVM with extraordinary efficiency and uniformity. The protein responsible for mitochondrial association has been identified and dubbed MAF1 for 'mitochondrial association factor 1'. This is a dense granule protein that is somehow presented on the host cytosolic face of the PVM where it can bind to host mitochondria. Remarkably, this protein differs between strains and, as a result, not all strains show the mitochondrial association. This difference appears to have an important effect on the host cell's response to the infection, in terms of cytokines produced.

Thus, through the PV, the parasite is able to create the ideal environment for its own growth, which then occurs with considerable efficiency (e.g., a doubling time of as little as 6 h for some strains under ideal conditions *in vitro*). Division is not by simple binary fission, however. Instead, the parasite undergoes a complex process known as endodyogeny (Figure 4). This term was chosen to convey the fact that two daughter parasites develop within the mother cell, dividing up the organelles between them or creating sets of entirely new ones. Midway through endodyogeny, some organelles that are made *de novo* are found as three distinct sets, being one new set for each of the daughter cells and one old set still in the mother cell. The inner-membrane complex and the rhoptries are examples of this situation. Most organelles, however, are only ever present with a complement of at most two, for example, the nucleus, the mitochondrion, the Golgi apparatus, and the plastid, all of which divide conventionally and flow into the two daughter cells as they develop.

Figure 4 Endodyogeny during asexual reproduction. Endodyogeny involves the creation of two daughter cells within a mother cell. As the two daughters develop from the anterior end backward, the apicoplast and the nucleus divide, and new rhoptries, and inner-membrane and apical complexes, appear. Eventually, the mother cell's organelles, including her plasma membrane, are fully co-opted by the daughters, except for the mother's inner-membrane complex, which mysteriously disappears.

Egress

The final stage of the lytic cycle, egress, is also the least studied. The intuitively appealing notion that the parasite's replication simply fills the host cell to the bursting point is argued against by the following data:

1. Video microscopy clearly shows that the parasites become highly motile just prior to egress suggesting a signal is delivered that initiates the exit process.
2. Egress can be artificially stimulated by various treatments including adding calcium ionophores to the medium, such as A23187, or strong reducing agents, such as dithiothreitol. This effect can be achieved as soon as 30 min after invasion (i.e., when there is only a single parasite per vacuole).

The simplest explanation is that in the natural cycle, as the parasite numbers grow, a critical concentration of a key molecule in the vacuolar space is reached, which then sends a signal to initiate the cascade of events leading to egress. This molecule would likely be freely diffusible (through the pores described above), thus explaining why the total number of parasites within a given cell is important rather than the number within a given vacuole. Hence, an infected cell harboring four vacuoles each with eight parasites will be lysed at roughly the same time as one infected with a single vacuole containing approximately 32 parasites.

Population Biology

Major Genotypes

In recent years, the population biology of *T. gondii* has come under intense scrutiny through studies of isoenzymes, restriction-fragment-length-polymorphisms (RFLP), microsatellite analysis, and direct genome sequencing. Out of these studies a very clear, consistent, but surprising picture has emerged. First, despite the existence of the well-described sexual cycle in cats, the parasite appears to be reproducing largely clonally. That is, a large fraction of strains come under one of only a few distinct genotypes. In fact, looking at samples from humans and domestic animals/livestock in Europe and North America, reveals the vast majority of strains come under one of just three genotypes (referred to as 'Type' I, II, or III, respectively).

Because *T. gondii* is haploid, this does not necessarily mean that the sexual cycle is not occurring. Instead, it could mean that the mating that does occur is almost entirely between individuals of the same genotype ('selfing'). This is not unreasonable, given that a single haploid tachyzoite can ultimately (via an infected mouse) give rise to a full sexual cycle in the cat, including genetically identical micro- and macrogametes, and thus the parasite does not have fixed mating types or sexes. Moreover, it is known that once a cat is infected, oocysts appear in the feces for about 1–2 weeks but thereafter, the cat is relatively immune to further infection and oocyst shedding decreases precipitously. Whether a cat infected with strain A and subsequently some weeks later with strain B will yield A/B recombinant progeny has not been directly examined but all available data suggest the answer will be no. These factors alone could account for the rarity of recombinants.

There is a second possible explanation for the clonal propagation: cats may play little if any role in the transmission of some strains. For example, it has been noted that Type I strains grown in the laboratory are difficult to pass in cats. As cats are the only known host in which the sexual cycle occurs, a loss of this function would require exclusively asexual expansion with transmission through carnivorous/scavenging or, perhaps, vertically in some host species.

The above could explain why most strains appear to be expanding clonally but why do most strain infecting domestic animals in North America and Europe belong to one of only three genotypes? For one of the most common protozoan parasites on earth (at least in terms of warm-blooded animals), it is hard to imagine that a major 'bottle-neck' in the population has ever occurred; that is, it seems doubtful that virtually all individuals in the *Toxoplasma* population were eliminated and only a few survivors went on to reestablish the species with their specific (chance) genotype. Instead, it appears that the three 'types' that have arisen are remarkably successful recombinants that have been selected for their ability to thrive in today's environment and that there is also a small but important population of recombinant parasites that collectively possess tremendous genetic diversity. Support for this hypothesis comes from the fact that when strains are isolated from other regions or from other species (e.g., South American wild monkeys or North American sea otters), very different genotypes can be found. Such studies have indicated the existence of at least 12 discrete lineages that represent a large pool of genetic diversity upon which the species can draw.

Strain-Specific Virulence

The three major types of this parasite found in Europe and North America are not just minor or random polymorphic states. Indeed, one of the first clues that the population biology of *T. gondii* was unusual was that the virulence of multiple different strains, when measured as the dose that resulted in a lethal infection in mice (LD_{100}) was either a single parasite or more than a thousand without a substantial middle ground. We now know that in susceptible mice, the so-called Type I parasites are highly virulent whereas Types II and III are relatively avirulent.

Recently, crosses between the three types have been used to identify some of the genes responsible for the differences in virulence. Several such genes have so far been identified and found to encode a number of polymorphic secreted proteins, including four paralogous ROPs, ROP5, ROP16, ROP18 and ROP38. ROP18 is a serine/threonine kinase that phosphorylates a set of host proteins in mice, including a group known as immunity-related GTPases or IRGs. IRGs are induced by $IFN\gamma$ and normally attack the vacuole containing intracellular parasites resulting in death of the parasites within; phosphorylation, however, results in their

inactivation. ROP5 helps ROP18 by binding the IRGs, thereby maintaining them in a monomeric state and making them available for phosphorylation. There are major differences in ROP5 and ROP18 in the three canonical types of *Toxoplasma* and these differences account for a significant amount of their difference in virulence. ROP5 is actually encoded by a set of 4–10 tandemly repeated genes; some of these genes appear to encode the same protein, while others encode distinct versions. The result is a very diverse set of proteins within and between strains, perhaps to match the diversity of the IRGs seen in rodents (curiously, humans are among the many species that do not have IRGs of the sort discussed here).

ROP16 is a polymorphic tyrosine kinase that is also injected into a host cell. In this case the targets are STATs ('signal transducers and activators of transcription') which are key to turning the immune response up or down. Again, the three canonical types differ in the ROP16 allele they carry with a resulting difference in how the host cell responds to infection. ROP38 is another serine/threonine kinase encoded by another tandemly repeated set of genes. In this case, the target appears to be mitogen-activated protein (MAP) kinase pathways.

Dense granules also release several polymorphic 'effectors' into the host cell during and after invasion. GRA15 differs between strains and somehow influences a potent host transcription factor known as NF κ B. GRA16 binds host HAUSP deubiquitinase and PP2A phosphatase to influence the key tumor suppressor p53. GRA24 binds host p38 MAP kinase, another key signaler in the host cell. These latter two GRAs do not seem to be measurably different in their effect between strains, although that could be because the experiments were not done in a host species or cell type where the differences would manifest.

The above results, especially with the strain-specific effectors, beg the question of what evolutionary pressures have led to these three canonical strains of *Toxoplasma* differing in virulence, at least in laboratory mice. One obvious possibility is that each strain evolved in association with a specific intermediate host (e.g., mice or sparrows) and is optimized for infection/transmission in that host species. When changes in the environment present such a strain with the opportunity to infect a new host species, it may do so but with a very different outcome from infection in its natural host. It seems unlikely, for example, that the Type I strain could have evolved as a natural infection of mice, given its extreme virulence in that species. Instead, it may have evolved with birds as its natural host and be very unsuited to infect mice. A corollary of this is that the serious consequences that result from such infections are not the result of selection because this combination of parasite strain and host species is a dead end (just as essentially all infections with *Toxoplasma* are in humans).

There is very little information on how differences in mouse virulence correlate with disease outcome in humans and livestock. The reason is that the knowledge that there are a limited number of strains is still relatively new and methods to distinguish them have been tedious and/or only recently applied. Nevertheless, some studies have been done and the data suggest that Type I and some non-canonical strains may be more virulent in otherwise healthy humans as well. In the absence of information on what strains are present in asymptomatic infections, however, and on what is the relative frequency of different types in the various animal reservoirs of human infection, it is impossible to draw any definitive conclusions about relative virulence. Determining whether strain type is an important factor in the severity of human infection is an important future goal of *Toxoplasma* researchers.

Host Immune Response

Nature of the Host Response

The innate immune system is well able to recognize *Toxoplasma*, at least certainly tachyzoites (on which virtually all such experiments have been performed) and presumably bradyzoites and sporozoites, as well (the latter being the first form seen by a naïve host). This recognition occurs within the first immune cells to be infected (e.g., dendritic cells and macrophages) and may be mediated by members of the toll-like receptor family such as TLR2, TLR4, TLR7 and TLR9. In mice, TLR11 and TLR12 (missing in humans) are especially important in this response. Interestingly, the TLR11 gene is defective in humans, and it has been speculated that this state is a result of evolutionary selection against an over-reaction to a *Toxoplasma* infection that is usually not serious. These TLR responses lead to generation of IL12 which, in turn, causes production of IFN γ from neutrophils, natural killer (NK) cells and T cells. The IFN γ is key to generating the inflammatory response necessary to contain the infection. Based on the use of antibodies that selectively deplete different T-cell subsets and/or mice that are deficient in these cells, it is clear that CD8+ cytotoxic T cells are among the most important effectors. Their action is augmented by a potent Th1-type response facilitated by CD4+ T cells. Serum antibodies likely also play some role in protecting against infection but these appear to be less important than T-cell responses, as might be expected for an infectious agent that grows exclusively within host cells.

Recent results have indicated that inflammasome activation downstream of Nod-like receptors (NLRs) is also key to the innate immune response to *Toxoplasma*, especially NLRP1 which is activated directly in infected cells and NLRP3 which may be a more general response to parasite-induced damage. Once triggered, the inflammasome generates IL-1 β , a key cytokine that plays a central role in the inflammatory response. In addition, inflammasome activation also can drive cells into pyroptosis, a form of inflammatory death and this could be an important protective mechanism as death of the infected host cells results in death of the parasite within.

Despite these robust immune responses that effectively control the acute (tachyzoite) stage of the infection, most animals and humans appear unable to clear the infection completely. Instead, tissue cysts containing bradyzoites persist for the life of the host in many parts of the body but most notably the brain, perhaps due to the very different nature of the immune response in this organ as well as the fact that the bradyzoites are within a cyst within a neuron and are antigenically distinct from tachyzoites. All these factors likely explain their refractoriness to immune clearance.

Genetics of Host Susceptibility

There is some information to indicate that in mice, at least, there is a genetic component that influences the outcome of infection. C57Black/6 mice are especially prone to an overexuberant immune response to oral infections by Type II parasites. The reasons why this particular combination of route of infection and host and parasite genotype results in such severe disease are not known but other experiments have revealed that the key T-cell epitope in Type II parasites comes from a particular allele of GRA6 that is only recognized by major histocompatibility complex (MHC) class I H2-d whereas C57Black/6 mice are H2-b haplotype. Thus, in addition to the strain-specific, biochemical impact of the polymorphic effectors described above (ROP16, GRA15, etc.), particular pairings of polymorphic parasite antigens and host antigen-presentation molecules also influence the progress of an infection.

In humans, there are also data to suggest that MHC plays a role in infection, at least in the context of toxoplasmosis in AIDS patients, but the effect is relatively small and the basis of the effect is unknown.

Immunization Studies

Immunization with crude or purified antigens (e.g., SAG1) or with attenuated strains (e.g., the temperature-sensitive ts4 mutant) can elicit a protective response. Efforts have also been made to use a mutant strain that is unable to complete the sexual cycle in cats. It generates a good immunity in the cat while not producing oocysts and would thus be relatively safe. The best studied attenuated strain was generated by deletion of the gene for carbamoyl phosphate synthase (*CPS*), resulting in uracil auxotrophy (i.e., *cps* mutants cannot grow unless excess exogenous uracil is added to the medium and so, while they can be grown *in vitro*, they will not productively infect an animal). None of these approaches or strains, however, has yet been developed for commercial use.

A commercial vaccine does exist based on the S48 strain, which was serially passed 3000 times through mice. This strain will produce an infection in sheep, which, once cleared, results in an immunity that reduces the problems associated with subsequent infection during pregnancy of the ewes (i.e., abortion). The strain apparently is completely cleared from the infected animals with no tissue cysts developing. Thus vaccination with this strain should not represent a problem if the sheep is subsequently slaughtered for consumption as no transmission to humans should be possible. Likewise, death of the vaccinated sheep in the field should not result in the strain entering the food chain through being ingested by scavengers.

Effect on Behavior

Experiments in rodents have clearly established that a chronic infection, which includes development of tissue cysts within the brain, can result in a marked change in behavior. These changes include increased activity that may make the animals more likely prey for cats because felines are attracted by motion of the prey. Even more intriguingly, several laboratories have reported that infected rats lose their innate fear of cats as demonstrated by their willingness to go where cats have urinated. This too would have obvious evolutionary benefit to the parasite in terms of increasing the probability of transmission. Unfortunately, it is impossible to test experimentally whether this is the real reason for these phenomena but such is an enticing possibility.

The notion that human behavior might be affected in people harboring a chronic infection has not been carefully examined but there are some epidemiological hints that this might be the case. As with most human studies, however, it is extremely difficult to tease out causation from correlation and confounding variables abound in most of the studies. Hence, while an intriguing and important possibility, existing data in support of an effect of *Toxoplasma* infection on human behavior are not yet compelling.

Prospects for Future Improvements in Controlling Toxoplasmosis

Public Health

Educating the public about this disease and ways to avoid it continue to be crucial goals. The clarity of the message would be hugely helped if we better understood the relative contribution to human infection of the two different routes of transmission (undercooked meat containing bradyzoites vs. accidental ingestion of oocysts contaminating water, garden vegetables, hands, etc.). Such information would allow the public health message and control measures to be focused on whichever route proves to be the more serious risk.

Information about which *Toxoplasma* strains cause the most serious disease would also be a huge help in the clinical management of the patient (e.g., in balancing between the use of potentially toxic drugs and the likely disease outcome if the infection is left untreated). Such improvements will depend on the development of diagnostic methods that distinguish between strains and source of the infection. Serological tests that distinguish between people infected with the different 'types' of *Toxoplasma* have begun to be developed but are not yet at the point where they have proven to be clinically useful.

Vaccination

Although there can be little doubt that a human vaccine could be developed, the relative rarity of serious human disease (especially compared to the number of people infected) and the fact that such disease is largely restricted to pregnancy or AIDS make testing and use of such a vaccine extremely difficult. Nevertheless, vaccines could have a tremendously important role to play because we are dealing with a zoonosis: *Toxoplasma* is not passed from human to human but instead is acquired from animals. Thus successful vaccination of these animals would be very effective in preventing human infection. The fact that *Toxoplasma* infection in sheep is a major cause of abortion in these animals adds a commercial incentive for the farmer, which provides further motivation for development of an animal vaccine. This could take the form of a recombinant subunit vaccine based on heterologous expression of the genes for one or more of *Toxoplasma*'s major antigens. Alternatively, the relative ease with which the parasite can be genetically manipulated makes possible the creation of a specifically engineered, attenuated mutant that would give rise to a high level of immunity without being pathogenic or transmissible from one host to another. The more traditional approach of serial passaging a strain to attenuate it has been used to create the S48 strain of *Toxoplasma* mentioned above. In the future, specifically engineered strains are likely to replace S48 because of the greater confidence that comes with knowing the attenuation is due to specific deletions that are non-reverting and can be confidently predicted to confer an attenuated state in any host.

Chemotherapy

Existing drugs are far from benign and/or are limited in their efficacy, especially against the chronic bradyzoite stage. The recent explosion in our understanding of the parasite's metabolism and cell biology, combined with concomitant improvements in the area of drug design, bode extremely well for the development of safer and more effective drugs. The fact that such drugs might also work on related Apicomplexan parasites such as *Eimeria* (the cause of chicken coccidiosis) and *Plasmodium* (the cause of human malaria) provides further incentive for efforts in this direction.

Glossary

–10 element A consensus sequence centered about 10 bp before the start point of transcription that is involved in the initial melting of DNA by RNA polymerase.

–35 element A consensus sequence centered about 35 bp before the start point of transcription that is involved in the initial recognition by RNA polymerase.

promoter A sequence of DNA whose function is to be recognized by RNA polymerase to initiate transcription. A typical *Escherichia coli* promoter contains two conserved elements, a –10 element and a –35 element (see above).

RNA polymerase The enzyme that synthesizes RNA using a DNA template (also termed DNA-dependent RNA polymerase).

sigma (σ) factor A subunit of bacterial RNA polymerase needed for initiation. The σ factor has major influence on the selection of promoters.

start point The position on the DNA that corresponds to the first base transcribed into RNA.

terminator A DNA sequence that causes RNA polymerase to terminate transcription and to dissociate from the DNA template.

transcription The synthesis of RNA on a DNA template.

transcription factor A protein needed to activate or repress transcription but is not part of the RNA polymerase enzyme.

transcription unit The DNA sequence that extends from the promoter to the terminator; it may include more than one gene

Abbreviations

asRNA	Antisense RNA;
CAP	Catabolite gene-activator protein;
H-NS	Histone-like nucleoid structuring protein;
IHF	Integration host factor;
mRNA	Messenger RNA;
NAPs	Nucleoid-associated proteins
Nus	N-utilization substance
RBS	Ribosome binding site
RNAP	RNA polymerase
rRNA	Ribosomal RNA
sRNA	Small RNA
tRNA	Transfer RNA

Defining Statement

The first step in gene expression is the transcription of the coding DNA sequences to discrete RNA molecules. Specific DNA regions, defined as promoters, are recognized by the transcribing enzyme, a DNA-dependent RNA polymerase (RNAP). The RNAP binds to the promoter and initiates the synthesis of the RNA transcript. The enzyme catalyzes the sequential addition of ribonucleotides to the growing RNA chain in a template-dependent manner until it comes to a termination signal ('terminator'). The DNA sequence between the start point and the termination point defines a 'transcription unit'. An RNA transcript can include one gene or more. Its sequence is identical to one strand of the DNA, the coding strand, and complementary to the other, which provides the template. The base at the start point is defined as +1 and the one before that as –1. Positive numbers are increased going downstream (into the transcribed region), whereas negative numbers increase going upstream. The immediate product of transcription, which extends from the promoter to the terminator, is termed as 'primary transcript'. In prokaryotes, messenger RNA (mRNA) is usually translated concomitantly while being transcribed and is rapidly degraded when not protected by the ribosomes, whereas ribosomal RNA (rRNA) and transfer RNA (tRNA) are cleaved to give mature products and are stable.

[☆]*Change History:* July 2014. Govindarajan S and Amster-Choder O included an Abstract, added and updated paragraphs, which review recent findings, throughout all the sections, added and updated Further Reading and Relevant Websites, and updated Key words and Abbreviations.

This article is an update of O. Amster-Choder, Transcriptional Regulation, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 501–516.

Transcription is the principal step at which gene expression is controlled. Many factors, such as DNA signals, regulatory proteins, noncoding RNAs, and small ligands (nucleotides, metabolites), determine whether the polymerase will choose to transcribe a certain gene and whether the whole process of transcription will be accomplished successfully. The timing of transcription of specific genes is influenced by environmental conditions and by the growth cycle phase.

The molecular picture of how genes are transcribed and the nature of the regulatory mechanisms that control transcription are far from being complete, but lots of progress has been made. Work on relatively simple organisms, bacteriophage, and bacteria has provided new insights into the mechanisms that are involved in the regulation of gene expression, transcriptional control mechanisms being among them. Although there are significant differences in the organization of individual genes and in the details and the complexity of the regulatory mechanisms among prokaryotes and eukaryotes, it is clear that basic principles are shared among all organisms. Due to the relative simplicity of prokaryotic biochemical pathways, their easy manipulation in the laboratory, and the advanced tools that are available for changing their genotype and for testing the resulting phenotype, it is easier to infer these basic principles by studying prokaryotes.

The Transcription Machinery

RNA Polymerase Catalyzes Transcription

RNA synthesis is catalyzed by the enzyme RNA polymerase (RNAP). The reaction involves the incorporation of ribonucleoside 5' triphosphate precursors into an oligoribonucleotide transcript, based on their complementarity to bases on a DNA template. RNAP catalyzes the formation of phosphodiester bonds between the ribonucleotides. The formation of a phosphodiester bond involves a hydrophilic attack by the 3'-OH group of the last ribonucleotide in the chain on the 5' triphosphate of the incoming ribonucleotide. The incoming ribonucleotide loses its terminal two phosphate groups, which are released in the form of pyrophosphate. In this manner, the RNA chain is synthesized from the 5' end toward the 3' end.

Multisubunit RNAPs are remarkably conserved in fundamental structure and mechanism. The best characterized RNAPs are those of eubacteria, for which *Escherichia coli* is a prototype. Unlike eukaryotic cells, in which various types of polymerases are dedicated to the synthesis of the various types of RNA, in eubacteria a single type of polymerase appears to be responsible for the synthesis of messenger RNA (mRNA), ribosomal RNA (rRNA), and transfer RNA (tRNA).

The dimensions of bacterial RNAP are approximately 90–95–160 Å. The molecular weight of the complete *E. coli* enzyme is approximately 465 kDa. About 7000 molecules of RNAP are present in an *E. coli* cell, but the number of molecules engaged in transcription at any given time varies from 2000 to 5000, depending on the growth conditions.

The DNA sequence that is being transcribed by RNAP is transiently separated into its single strands, with one of the strands serving as a template for the synthesis of the RNA strand. This region is therefore defined as the 'transcription bubble'. As the RNAP moves along the DNA, it unwinds the duplex at the front of the bubble and rewinds the DNA at the back, so that the duplex behind the transcription bubble reforms. Thus, the bubble moves with the RNAP, and the RNA chain is elongated. The length of the transcription bubble varies from 12 to 20 bp. The length of the transient hybrid between the DNA and the newly synthesized RNA sequence within the transcription bubble is a matter of controversy and the estimates range from 2 to 12 nt. Beyond the growing point, the newly synthesized RNA chain enters a high-affinity binding site within the RNAP.

Bacterial RNA Polymerase Consists of Multiple Subunits

The RNAPs of certain phage consist of single polypeptide chains. These polymerases recognize a very limited number of promoters and they lack the ability to change the set of promoters from which they initiate transcription. In contrast, bacterial RNAPs consist of several subunits. The most studied bacterial RNAP, the one in *E. coli*, exists in two forms, an holoenzyme and a core enzyme. The holoenzyme is capable of selective initiation at promoter regions, whereas the core RNAP is capable of elongation and termination, but not selective initiation. The two forms of the polymerase consist of two identical α -subunits, one β -subunit, and one β' -subunit, but only the holoenzyme contains an additional subunit, one of the several σ proteins. The subunit composition of the holoenzyme is summarized in Figure 1. The α -subunit plays an important role in RNAP assembly, which proceeds in the pathway $\alpha \rightarrow \alpha_2 \rightarrow \alpha_2\beta\beta' \rightarrow \alpha_2\beta\beta'\sigma$. The α -subunit plays some role in promoter recognition and in the interaction of RNAP with transcriptional activators (see later). The β and β' subunits together constitute the catalytic center of RNAP. The β -subunit was demonstrated to contact the template DNA, the newly synthesized RNA, and the substrate ribonucleotides. The β' -subunit contacts the RNA chain as well. Mutations in the genes that encode β and β' show that both subunits are involved in all stages of transcription. The sequences of β and β' show homology to the sequences of the largest subunits of eukaryotic RNAPs. This conservation through the evolution hints that the mechanisms by which all RNAPs catalyze transcription share common features. In accord, high-resolution structural studies on the core enzyme show that it adopts a certain structure, which is similar to the structure that is found in the yeast RNAP II. The assignment of individual functions to the different subunits of the core polymerase is only a rough estimation because most probably each subunit contributes to the activity of the enzyme as a whole. In addition, a small 91-residue protein, termed the ω subunit, associates with the polymerase. It has no direct role in transcription, but seems to function as a chaperone to assist the folding of the β' subunit.

The σ subunit has three main functions: to ensure the recognition of specific promoter sequences; to position the RNAP holoenzyme at a target promoter; and to facilitate unwinding of the DNA duplex near the transcript start site. Based on recent studies, ' σ ' subunits are involved also in other aspects of transcription initiation, such as abortive initiation and promoter escape.

Figure 1 *E. coli* RNA polymerase holoenzyme consists of four types of subunits.

There are several types of σ factors in the bacterial cell (see later). The major σ factor in *E. coli*, which is required for most transcription reactions, is σ^{70} . Although σ^{70} has domains that recognize the promoter DNA sequence, as an independent protein, it does not bind to DNA, perhaps because its DNA-binding domain is sequestered by another domain of the σ^{70} molecule (when σ^{70} is shortened from its N-terminus, it is able to bind to DNA, suggesting that the N-terminal region has an inhibitory effect on the ability of σ^{70} to bind to DNA). However, upon binding to the core enzyme and the formation of the holoenzyme complex, σ^{70} undergoes a conformational change and it now contacts the region upstream of the start point. The dogma is that the σ factor discharges from the core enzyme when abortive initiation is concluded and RNA synthesis is successfully initiated (although findings suggest that, at least in some cases, σ can remain associated with the polymerase during postinitiation steps). The released σ factor becomes immediately available for use by another core enzyme, although the activity of many σ factors is controlled by an anti- σ factor, which sequesters it away from the RNAP. *E. coli* cells contain about 3000 molecules of σ^{70} , enough to bind about one-third of the intracellular core RNAP.

The Ability of RNA Polymerase to Selectively Initiate Transcription is Dependent on the Presence of σ Factor

Bacterial polymerases have to recognize a wide range of promoters and to transcribe different genes on different occasions. Specificity of gene expression is in part modulated by substituting one species of σ for another, each specific for a different class of promoters. In *Bacillus subtilis*, σ factors are implicated in the temporal regulation of sporulation. In *E. coli*, alternative σ factors are used to respond to general environmental changes. The σ factors are named either by their molecular weight (e.g., σ^{70}) or after their genes, which are usually termed 'rpo' (e.g., RpoD for σ^{70}). Sigma factors are subdivided into σ^{70} class or σ^{54} class on the basis of homology as well as the mechanism of action. Members of the σ^{70} class are active immediately upon binding to the core RNAP and to the DNA, and are regulated either by modulating the amount of expression or by the action of anti-sigma factors. Members of the σ^{54} class require an additional ATP-dependent activation event provided by one of several AAA⁺ ATPase transcriptional activators and are, therefore, subjected to an additional level of regulation.

When cells are shifted from low to high temperature, the synthesis of a small number of proteins, the heat-shock proteins, transiently increases. The σ^{32} protein (RpoH) is responsible for the transcription of the heat-shock genes. The basic signal that induces the production of σ^{32} is the accumulation of unfolded proteins that results from the increase in temperature. The heat-shock proteins play a role in protecting the cell against environmental stress. Several of them act like chaperones, preventing the unfolding (denaturation) of proteins. The heat-shock proteins are synthesized in response to other conditions of stress, implying that the production of σ^{32} is induced also by conditions other than elevation in temperature. The level of σ^{32} is strictly controlled by various mechanisms. First, σ^{32} protein is unstable and is rapidly degraded when it is not needed. Second, the mRNA of σ^{32} forms a secondary structure that represses translation, but at higher temperatures, that is during heat shock, the secondary structure of the mRNA is relieved resulting in translation of σ^{32} . Third, σ^{32} is regulated by phosphorylation. Finally, σ^{32} was recently shown to localize to the inner membrane of *E. coli* cells, and this localization was found to be important for its proper regulation in response to the protein folding status in the cell during heat shock conditions. Another σ factor, σ^E , appears to respond to more extreme temperature shifts that lead to the accumulation of unfolded proteins, which are usually found in the periplasmic space or the outer membrane. Less is known about this σ factor and about the genes it controls.

When *E. coli* and other enteric bacteria are nitrogen-limited, the synthesis of a number of proteins is dramatically induced. The increased production of these proteins enlarges the capacity of cells to produce nitrogen-containing compounds, and to use nitrogen sources other than ammonia. The transcription of the genes that encode these proteins is dependent on σ^{54} (also known as σ^N). σ^N

is also involved in nitric oxide stress response. Expression of the flagellar genes under normal conditions depends on σ^{28} (also known as σ^F). σ^{19} (FeC) is a minor sigma factor that regulates expression of genes involved in transport of ferric citrate.

When *E. coli* cells are starved, they shift from the exponential-growth phase to the stationary phase. The ability of the cells to cope with starvation depends on the production of many proteins. This is enabled due to the synthesis of σ^S (RpoS), which transcribes the relevant genes. Similar to σ^{32} , σ^S is also subjected to multiple levels of regulation, which involve proteolysis, small RNAs and small molecules. Unlike *E. coli*, when *B. subtilis* cells are starved, they can form spores. Sporulation involves the differentiation of a vegetative bacterium into a mother cell and a forespore; the mother cell lyses and a spore is released. The process of sporulation involves a drastic change in the biosynthetic activities of the bacterium, in which many genes are involved. This complex process is concerted at the level of transcription. The principle is that in each compartment (the mother cell and the forespore) the existing σ factor is successively displaced by a new σ factor that causes the transcription of a new set of genes. Communication between the compartments occurs in order to coordinate the timing of the changes in the mother cell and the forespore.

The promoters identified by the various σ factors are organized similarly, having their important elements centered around 10 and 35 nt upstream from the start point (see later), except for σ^{54} , whose promoters have slightly different characteristics. However, the ability of different σ factors to cause RNAP to initiate at different sets of promoters stems from the fact that each type of σ factor recognizes promoter elements with unique sequences. σ^{54} differs from the other σ factors also in its ability to bind to DNA independently, and by the influence of sites that are distant from the promoter on its activity. In many aspects, σ^{54} resembles eukaryotic regulators.

A comparison of the sequences of the different σ factors identifies four regions that have been conserved. Several sequences in these regions were identified with individual functions, such as interaction with core RNAP or contacting the various promoter elements. Recent structural information shows that two key σ domains are structurally conserved, even among diverse family members.

Template Recognition: Promoters

Promoter Recognition Depends on Conserved Elements

Template recognition begins with the binding of RNAP to the promoter. Promoter is a sequence of DNA whose function is to be recognized by RNAP to initiate transcription. The information for promoter function is provided directly by the DNA sequence, unlike expressed regions, which require that the information be transferred into RNA or protein to exercise their function. Two main approaches were used to identify the DNA features that characterize a promoter. The first is comparative sequence analysis and the second is the identification of mutations that alter the recognition of promoters by RNAP. Comparison of the sequence of many *E. coli* promoters recognized by the major RNAP species, σ^{70} holoenzyme, revealed an overall lack of extensive conservation of sequence over the 60 bp associated with RNAP. Nevertheless, statistical analysis revealed some commonalities. A typical *E. coli* promoter that is recognized by σ^{70} contains four conserved features: the start point, the -10 region, the -35 region, and the distance between the -10 and -35 regions. The start point is usually a purine. It is often the central base in the sequence CAT, but this is not a mandatory rule. The -10 region is a hexanucleotide that centers approximately 10 bp before the start point, although this distance is somewhat variable. Its consensus sequence is TATAAT (in the antisense strand). The conservation is T80 A95 T45 A60 A50 T96, where the numbers refer to the percent occurrence of the most frequently found base at each position. The -35 region is a hexanucleotide sequence that centers approximately 35 bp upstream of the start point. Its consensus is TTGACA and the conservation is T82 T84 G78 A65 C54 A45. The favored spacing between the -10 and the -35 sequences is 17 bp.

For most promoters, there is a good correlation between promoter strength and the degree to which the -10 and -35 elements agree with the consensus sequences. The significance of the conserved promoter features was further emphasized by the finding that most mutations that alter promoter activity (i.e., affect the level of expression of the gene(s) under the control of this promoter) change the sequence of the particular promoter in an expected fashion. Mutations that increase the similarity to the proposed conserved -10 and -35 sequences or bring the spacing between them closer to 17 bp, usually, enhance the promoter activity ('up mutations'); mutations that decrease the similarity to the conserved sequences or bring the spacing between them more distant than 17 bp, usually, reduce the promoter activity ('down mutations'). The nature of down mutations in the -35 and -10 regions of various promoters led to the conclusion that the -35 region is implicated in the recognition of the promoter by RNAP and the formation of a closed transcription complex, whereas the -10 region is implicated in the shift of the closed complex to the open form (see later). The fact that the -10 region is composed of AT base pairs that require low energy for melting makes it suitable to assist in unwinding and, thus, in converting the transcription complex into its open form.

There are several exceptions to the proposed generalized pattern. For example, some promoters lack one of the conserved sequences, the -10 or the -35 region, without a corresponding effect on promoter activity. In some cases, it was proposed that another sequence compensates for the lack of a consensus sequence. In still other cases, it was concluded that the promoter cannot be recognized by RNAP alone, and the involvement of additional proteins that overcome the deficiency in intrinsic interaction between RNAP and the promoter is required. Other exceptional promoters were discovered due to the isolation of promoter mutations that do not affect any of the conserved promoter features described so far. Rather, they are the outcome of base substitutions in other sequences in the vicinity of the conserved sequences or the start point. One explanation for these findings is that the analysis that generated the sequence characteristics of a typical promoter may have missed some sites that contribute to the transcription initiation process, possibly because it included too many promoters, both weak and strong. Alternatively, other

base pairs in the promoter could be recognized by RNAP, but might become significant only if canonical recognition sites are absent.

The isolation of deletions that progressively approach specific promoters from the upstream region demonstrated the involvement of specific upstream sites in the recognition of RNAP in some cases. This led to the discovery that some *E. coli* promoters contain a third important element in addition to the -10 and -35 sequences. This element was named the upstream element, or 'UP element', because it is located approximately 20 bp upstream of the -35 region. Its sequence is AT-rich and it was first identified in the strong promoters of the *rnn* genes, which encode rRNA. It is believed now that promoter strength is a function of all three elements, -10 , -35 , and UP, with very strong promoters, such as the *rnn* promoters, having all three elements with near-consensus sequences and with weaker promoters having one, two, or three nonconsensus promoter elements. It has been found that, whereas -70 is responsible for the recognition of the -10 and -35 regions, the UP element interacts with the α -subunit of RNAP.

Finally, the activity of some promoters is affected by sequences downstream to the -10 region, or even downstream to the transcription start point. The sequences immediately around the start point seem to influence the initiation event. The effect of the initial transcribed region (from $+1$ to $+30$) on promoter strength is explained by the influence of this region on the rate at which RNAP clears the promoter. Unlike the promoters described so far, which are recognized by holoenzymes that contain σ^{70} or a close homologue, a minority of the cellular holoenzymes use σ^{54} and have different basal elements located at -12 and -24 . Transcription initiation from these promoters relies also on enhancer-like elements that are remote (upstream) from the promoters (see later).

Possible Mechanisms of Promoter Recognition

A typical *E. coli* cell contains approximately 3000 promoters and, as mentioned above, the number of RNAP molecules engaged in transcription at any given time varies from 2000 to 5000. How does RNAP find the promoter sequences? How does it identify a stretch of approximately 60 bp that defines a promoter in the context of 4×10^6 bp that make up the *E. coli* genome? Several models were suggested to explain the ability of RNAP to find promoters. The first model assumes that RNAP moves in the cell by random diffusion. It associates and dissociates from loose binding sites on the DNA until, by chance, it encounters a promoter sequence that allows tight binding to occur. According to this model, movement of an RNAP molecule from one site on the DNA to another is limited by the speed of diffusion through the medium. However, this parameter might be too low to account for the rate at which RNAP finds promoters. The second model addresses this problem by assuming that once an RNAP molecule binds to a DNA sequence, the bound sequence is directly displaced by another sequence; the enzyme exchanges sequences very rapidly, until it binds to a promoter that allows an open complex to form and transcription initiation to occur. According to this model, the association of the polymerase with DNA sequences and their dissociation are essentially simultaneous. Thus, the time spent on site exchange is minimal and the search process is much faster in comparison to the speed calculated based on the first model. This model fits the accepted notion that core polymerases that are not busy in transcription are stored by binding to loose sites on the DNA. The third model assumes that RNAP binds to a random site on the DNA and starts sliding along the DNA molecule until it encounters a promoter. Recently promoter recognition by RNAP in *E. coli* was suggested to involve a mechanism called 'three dimensional (3D) diffusion or jumping'. According to this model, free RNAP molecules in the solution search the promoter by 3D collisions with the DNA. This model takes into consideration the folding and compaction of bacterial chromosomes, which bring different genomic regions into close proximity. Of note, the presence of ample DNA-bound proteins might limit the 1D movement of RNAP in search for promoters, but not the 3D diffusion, making the 3D diffusion model an attractive one. However, the actual mechanism by which RNAP finds promoters might combine features of the various models.

Transcription Initiation

The activities of genes are frequently regulated at the initiation step of transcription. Therefore, the initiation of transcription is a very precise event that is tightly controlled by various regulatory mechanisms. Studying transcription initiation in *E. coli* has served as a model for understanding transcriptional control throughout all kingdoms of life.

Stages of the Transcription Initiation Process

Transcription initiation is the phase during which the first nucleotides in the RNA chain are synthesized. It is a multistep process that starts when the RNAP holoenzyme binds to the DNA template and ends when the core polymerase escapes from the promoter after the synthesis of approximately the first nine nucleotides.

The stages of the transcription initiation process, which are summarized in Figure 2, can be described in terms of the types of interaction between the RNAP and the nucleic acids that are involved. The first stage in transcription initiation is the formation of a complex between the holoenzyme and the DNA sequence at the promoter, which is in the form of a double-stranded DNA. This complex is termed a closed binary complex or *closed complex*. The second stage is the unwinding of a short region of DNA within the sequence that is bound to the RNAP. The complex between the polymerase and the partially melted DNA is termed an open binary complex or *open complex*. The conversion of the closed complex into the open complex leads to the establishment of tight binding between the RNAP and the promoter sequence. For strong promoters, the conversion into an open complex is irreversible. The third

Figure 2 Stages of the transcription initiation process.

stage is the incorporation of two ribonucleotides and the formation of a phosphodiester bond between them. Because the complex at that stage contains an RNA, as well as DNA, it is called an initiation *ternary complex*. Up to seven additional ribonucleotides can be added to the RNA chain without any movement of the polymerase. After the addition of each base, there is a certain probability that the enzyme will release the short (up to nine bases long) RNA chain. Such an unsuccessful initiation event is termed an 'abortive initiation'. Following an abortive initiation, RNAP begins again to incorporate the first base. Several rounds of abortive initiations usually occur and the result is the formation of short RNA chains that are 2–7 bases long. When initiation succeeds, that is, a nine-base-long RNA chain is formed and is not released, the last stage in transcription initiation occurs. At that stage the σ factor is released from the polymerase. As a consequence, a complex containing core polymerase, DNA, and RNA is formed. This complex is called an elongation ternary complex. The departure of the polymerase from the promoter to resume elongation is termed promoter escape or *promoter clearance*. Recently, nanoRNAs, which are 2 to 4 nucleotide long, were found to be important for priming of transcription initiation in vivo. These RNAs provide a basis for transcription start site selection and gene expression.

Transcription Factors

Regulation of transcription involves a complex network, where DNA-binding proteins, termed transcription factors, are a key component. Transcription factor is a protein needed to activate or repress the transcription of a gene, but is not itself a part of the enzyme. Some transcription factors bind to *cis*-acting DNA sequences only; some bind to each other; others bind to DNA as well as to other transcription factors. When a transcription factor binds to a specific promoter, it can either activate or repress transcription

initiation. Some transcription factors function solely as activators or repressors, whereas others can function as either according to the target promoter.

The *E. coli* genome contains more than 300 genes that encode proteins that are predicted to bind to promoters, and to either up- or down-regulate transcription. So far, about half of these have had their functions verified experimentally. Some of these proteins control large numbers of genes, whereas others control just one or two genes. It has been estimated that seven transcription factors (CRP, FNR, IHF, Fis, ArcA, NarL, and Lrp) control 50% of all regulated genes, whereas ~60 transcription factors control only a single promoter. Bacterial transcription factors can be grouped into different families on the basis of sequence analysis. So far, a dozen families have been identified, the best characterized of these being the LacI, AraC, LysR, CRP, and OmpR families. Because a large percentage of the polymerase molecules are occupied with transcription of ribosomal genes, transcriptional regulation of these genes is intensively studied. It has been shown that, in addition to σ^{70} -RNAP, the Fis and H-NS proteins bind near the upstream P1 promoter of the seven ribosomal transcription units and regulate transcription.

The activity of most bacterial promoters is dependent on multiple environmental cues, rather than just one signal. In most cases, for a promoter to respond to multiple signals, multiple transcription factors are required. Accordingly, many promoters are controlled by two or more transcription factors, with each factor relaying one environmental signal. However, in some cases a regulatory protein can 'integrate' multiple signals, like the NifL–NifA system in *Azotobacter vinelandii*, which controls the genes that are involved in nitrogen fixation in response to oxygen levels and the availability of carbon and nitrogen. There are a few examples of integrated regulation that are solely dependent on repressors, but, in most examples studied so far, complex regulation depends on combinations of repressors and activators or codependence on more than one activator.

Repression of Transcription Initiation

Gene expression is sometimes negatively regulated by a repressor protein that, when bound to DNA, inhibits transcription initiation. The ability of the repressor to bind to DNA is in turn modulated by the binding of an effector molecule to the repressor. The regulation of the *lac* operon expression in *E. coli* is a paradigm for this type of transcriptional control. LacI is a repressor protein that blocks the initiation of transcription from the promoter of the *lac* operon. LacI binds to a site on the DNA, termed an *operator*, that overlaps with the promoter. Because of this overlap, the binding of the LacI repressor and of RNAP are competitive events. That is, RNAP cannot bind to the promoter until the repressor is removed from the operator. The binding of one of several β -galactoside compounds to the repressor destabilizes the repressor–operator complex and allows RNAP to bind to the promoter to initiate transcription. Interestingly, the *lac* operon has two additional binding sites for LacI, an upstream site and a downstream site, located in the first gene of the operon. Compared to the operator, the additional sites have a lower affinity for the repressor protein and it was suggested that they do not directly participate in the inhibition of transcription initiation. Rather, the secondary binding sites seem to stabilize the repressor–operator complex.

There are important exceptions to the *lac* repression paradigm. An example is the repression of the *gal* operon transcription initiation by a different and less understood mechanism. The *gal* operon contains two repressor-binding sites, both required for maximum efficacy of the *gal* repressor, yet neither of these operators overlaps with the promoter sequences. Thus, the binding of the *gal* repressor to its operators does not seem to compete directly with binding of RNAP to the *gal* promoter. It was suggested that the *gal* repressor, when bound to both binding sites, holds the DNA in a conformation that is unfavorable for binding to RNAP.

Activation of Transcription Initiation

The frequency of transcription initiation from many promoters is enhanced by activator proteins. Activators improve the performance of a promoter by improving its affinity for RNAP. In most cases, they bind within or upstream from the promoter and make a direct contact with RNAP. The activators that interact with the most abundant form of RNAP involved in transcription initiation in *E. coli*, the σ^{70} holoenzyme, can be roughly divided into two groups, those that interact with the α -subunit of RNAP and those that interact with the σ^{70} subunit.

The best characterized activator from the first group is the catabolite gene-activator protein (CAP). The CAP target site on the DNA was determined in a number of systems. Comparative sequence analyses led to the definition of a consensus sequence for CAP binding. CAP-binding sites are found at various locations relative to the transcription start point in different systems. The most studied case is the activation of transcription initiation from the *lac* promoter by CAP. The regions that are required for the activation on both CAP and the α -subunit of RNAP were defined. CAP acts as a dimer, and although the activating region is present in both subunits of the CAP dimer, transcription activation at the *lac* promoter requires only the activating region of the promoter-proximal subunit. CAP interacts with the C-terminal domain of the α -subunit (α CTD). The α CTD constitutes an independently folded domain, which is connected to the remainder of α by a flexible linker. This allows α CTD to make different interactions in different promoters. The simplest model for transcription activation by CAP is that CAP binds to the DNA and recruits the α CTD, and thus the RNAP holoenzyme, to the promoter.

The best characterized activator from the second group is the cI protein of bacteriophage λ (λ CI). λ CI binds to a site on the DNA that overlaps the -35 element of the λ P_{RM} promoter. The activating region in λ CI was defined and was demonstrated to directly contact a specific region in σ^{70} .

The existence of at least two groups of activators that bind to separate targets on the DNA and to different components of RNAP raised the possibility, which was later proven, that, at some promoters RNAP might be contacted simultaneously by two or more

activators. Generally, where two transcription factors are involved, one factor interprets a global metabolic signal, whereas the other responds to a specific metabolic signal. The best illustration of this is the *E. coli lac* promoter, which is regulated by CRP that depends on a global signal, glucose starvation, and by the Lac repressor, which is controlled by a specific metabolite, allolactose. In most cases, multiple activators bind independently to their target promoters. However, there are a few promoters at which activators bind cooperatively.

In contrast to the copious σ^{70} promoters, the rare σ^{54} promoters, which contain –12 and –24 basal elements instead of the well-known –10 and –35 elements, seem to be regulated solely by activation rather than by repression. σ^{54} activators (the most studied is NtrC) bind to enhancer-like sites on the DNA; that is, the sites are remote from the promoters (upstream) and their precise location is not critical for transcriptional activation. In fact, these sites can be moved kilobases in *cis* and retain their residual function. Thus, unlike σ^{70} activators that bind to sites that enable direct communication with RNAP, σ^{54} activators, once bound to their DNA target sites, cannot touch the polymerase without looping out the intervening DNA. This seems to be the reason why σ^{54} promoters frequently require the help of integration host factor (IHF), which enhances the bending of the DNA, as a cofactor. It is accepted that σ^{54} polymerase can bind to its promoters to form a closed complex. However, this polymerase cannot transcribe because it cannot melt the DNA. Once the upstream activator binds to its target site upstream of the promoter, it loops out of the sequence between its binding site and the promoter and touches the complex. This interaction triggers the melting of DNA (with the help of a helicase activity) and the creation of a transcription bubble. Thus, σ^{54} activators catalyze the conversion of the polymerase–promoter complex from a closed state to a transcription-ready open state, rather than tethering the RNAP to the promoter.

One conclusion from studies with various types of activators is that many activators seem to function by helping recruit DNA-binding domains of RNAP to DNA, thus supplementing suboptimal RNAP–DNA interactions with protein–RNAP interactions. Apparently, most activators function by binding to target promoters before acting on RNAP. However, an alternative mechanism has been proposed for the MarA and SoxS regulators, in which they interact with free RNAP before binding to promoter DNA. In most cases, multiple activators bind independently at their target promoters. However, there are a few promoters at which activators bind cooperatively.

Small Ligands

Small ligands provide an alternative mechanism by which RNAP can respond quickly and efficiently to the environment. The best example is guanosine 3',5' bisphosphate, ppGpp, and also pppGpp, which are synthesized when amino acid availability is restricted to the extent that translation is also limited. Transcription of the seven transcription units that encode the rRNAs is mostly affected by the levels of ppGpp. A crystal structure shows that ppGpp binds near the catalytic centre of RNAP. This location might allow it to alter interactions with the incoming nucleoside triphosphates, with the catalytic magnesium and perhaps with the non-template DNA strand to destabilize open complexes. ppGpp has a co-regulator, the polymerase-binding DksA protein, which lowers the concentration of ppGpp needed to inhibit transcription. DskA exaggerates the effects of ppGpp by adapting the polymerase for regulation at promoters that are affected by the nucleotide. ppGpp also favors the association of other sigma factors with core polymerase at the expense of the σ^{70} holoenzyme that transcribes the ribosomal promoters. It has been proposed that ppGpp controls expression of the translation machinery in response to sudden starvation, whereas ATP availability controls expression in response to growth rate.

For obvious reasons, rRNA transcription is subject to complex regulation. Hence, in addition to the levels of ppGpp, the promoters of these genes respond to other factors, for example, they show an unusually high affinity for the first two nucleotides that form the 5' end of the ribosomal transcript. This property, which can be explained by the unusual features of the ribosomal promoters, allows selective inhibition of rRNA transcription when nucleotide concentrations decrease, as is the case in stationary phase. The net amount of rRNA transcription is a function of the ratio of inhibitors to activators – H-NS/Fis (see section 'Transcription factors') and ppGpp/NTP. Both of these ratios are usually highest during slow growth and lowest during rapid growth.

Small RNAs

A subset of small RNAs has been found to regulate transcription in bacteria. One example is the abundant 6S RNA that inhibits transcription at many σ^{70} -dependent promoters during stationary phase by binding to the active site of σ^{70} -RNAP and competing for DNA binding. The conserved secondary structure of 6S RNA, a single-stranded central bulge within a highly double-stranded molecule that is essential for 6S RNA function, has led to the proposal that 6S RNA mimics the open conformation of promoter DNA. Not only does 6S RNA block access to promoter DNA, but, surprisingly, it is used as a template for RNA synthesis. Synthesis of the templated RNA relieves the inhibitory effect of 6S RNA when cells encounter new nutrient sources and resume growth.

Recently, a new subset of RNAs, termed transcription start site-associated RNAs (tssRNAs), was identified in *Mycoplasma*, as well as in *E. coli*. The average size of tssRNAs is approximately 45 bp and they map to the beginning of certain full length transcripts. The tssRNAs appear to be synthesized through cryptic promoters and are not formed as a result of RNA degradation or abortive transcription. Although the regulatory function of tssRNAs is currently not known, their increased synthesis during stationary phase,

a phenomenon not observed for their cognate full length mRNAs, suggests a potential role for tssRNAs in transcriptional reprogramming.

Antisense RNAs

Antisense RNAs (asRNAs) are complementary to mRNAs that are encoded by the opposite DNA strand, thus providing means for regulation. Using ultra-sequencing technologies, it was found that in *E. coli* nearly 20% of genes encode asRNAs. These RNAs are implicated in transcription initiation through a process called transcription interference, which is a phenomenon whereby transcription at one strand affects or suppresses transcription from the opposite strand. This can occur if the promoters of the sense and antisense strands face each other and the regions that encode the transcripts on the two strands overlap. Thus, when asRNA is transcribed from a strong promoter on one strand, transcription is prevented from the promoter on the opposite strand. In such a scenario, the transcription process itself acts as a regulator and the asRNA is formed as a by-product. An example for this mode of regulation is provided by the convergent lytic promoter (pR) and lysogenic promoter (pL) of coliphage 186. Recently, dual purpose asRNAs were identified, which can function both as mRNAs and as asRNA. These RNAs, termed “excludons” are unusually long, spanning the length of an entire operon and extending into neighboring operons encoded by the opposite strand, thus regulating the expression of these opposite strand-encoded operons.

Regulation of Transcription Initiation via Changes in DNA Topology and Nucleoid-Associated Proteins (NAPs)

The template for transcription is a negatively supercoiled DNA. Because the formation of an open transcription complex requires DNA melting, and because the degree of superhelicity affects the energy needed for the melting, it was anticipated that the superhelical character of a template would affect the properties of this template. Indeed, the efficiency of some promoters is influenced by the degree of supercoiling. Most of these promoters are stimulated by negative supercoiling, although few are inhibited. The effects of superhelicity on the process of transcription initiation have been shown in vitro in numerous studies and in vivo by the use of inhibitors of gyrase, which introduces negative supercoils. The reason why some promoters are sensitive to the degree of supercoiling, whereas others are not, might have to do with the fact that the sequence of some promoters is easier to melt and is therefore less dependent on supercoiling. Alternatively, because various regions on the bacterial chromosome are believed to have different degrees of supercoiling, the location of the promoter might determine whether it is sensitive to changes in superhelicity.

An additional level of transcription regulation is achieved by the organization of the nucleoid. A collection of non-specific DNA binding proteins, termed Nucleoid Associated Proteins (NAPs), organize the bacterial nucleoid into higher order conformations that are reminiscent of the eukaryotic nucleosomes. Major proteins of this category include histone-like nucleoid structuring protein (H-NS), HU and Fis. Binding of NAPs induces conformational changes in the DNA, including bending, bridging and wrapping, which are known to affect transcription. HNS, an extensively studied NAP, which is specifically involved in silencing of horizontally acquired genes, binds to AT-rich sequences and affects transcription of nearly 5% of *E. coli* genes. The interplay between the NAPs is implicated in growth phase-dependent global transcription changes. Thus, during the exponential growth phase, ribosomal genes are brought together by NAPs to form looped DNA domains. This higher order nucleoid conformation is called ‘transcription factories’ since actively transcribing RNAP are concentrated at these loci.

Stochasticity and Bursting Behavior of Transcription Initiation

Monitoring single cells by advanced microscopy techniques have uncovered that transcription is a stochastic process, which is subject to random fluctuations between active and inactive states. As a result, the mRNA molecules are not produced at a constant rate, but are rather randomly produced during the active state periods. Furthermore, in the active state, the initiation event happens in a burst, leading to production of several mRNA molecules and then, for unknown reasons, a switch to a quiescence inactive mode occurs. The time it takes for two consecutive bursting events, as well as the number of mRNA molecules produced from each burst are also subjected to stochasticity. Thus, stochasticity in transcription creates heterogeneity in bacterial populations, which are otherwise considered homogenous. This heterogeneity in the number of mRNA molecules in different bacterial cells within a population is further exaggerated by the non-uniform distribution of mRNA molecules during cell division. Despite these observations, the physiological significance of transcription heterogeneity is currently not understood. Also, it is not known why the transcription apparatus chooses the quiescence or inactive mode at times, given that all the factors required for transcription are constantly present in the cell.

Promoter Occlusion in Transcription Initiation

In *E. coli*, the promoter region of certain genes contains sequences specific for more than one sigma factors. Such promoters are called overlapping promoters and the regulation of transcription initiation at these promoters are poorly understood. A recent study on the regulation of transcription of the gene for the σ^S activator Crl, which contains overlapping promoter sequences specific for σ^{70} and σ^{54} , revealed a previously unappreciated mechanism for regulating transcription initiation termed ‘promoter occlusion’.

In this process, transcription initiation from the σ^{70} promoter, which is the first of the overlapping promoters, results in formation of a functional transcript with proper ribosome binding sequence. Thus, translation of the transcript formed from the σ^{70} promoter produces the *crI* gene product. In contrast, under conditions of nitrogen limitation, σ^{54} is activated and transcription of the *crI* gene initiates at the σ^{54} promoter, which is the second of the overlapping promoters. Unlike the σ^{70} promoter, transcription of the *crI* gene from the σ^{54} promoter results in synthesis of a long non-coding RNA. This transcript lacks the ribosome binding sequence and, hence, is not translated. Summarily, promoter occlusion provides a novel regulatory strategy, whereby initiation from one promoter occludes initiation from the other promoter, thus down-regulating expression of the gene simply by producing a non-functional transcript.

Transcription Elongation

The initiation phase ends when RNAP succeeds in extending the RNA chain beyond the first nine nucleotides and escapes from the promoter. At that stage the elongation process begins and the enzyme starts moving along the DNA, extending the growing RNA chain. During the transition from initiation to elongation, the size and shape of the RNAP undergoes successive changes. The first change is the loss of the σ factor. Whereas the holoenzyme covers approximately 75 bp (from -55 to $+20$), after the loss of σ , the polymerase covers approximately 55 bp (from -35 to $+20$). At that stage the polymerase is displaced from the promoter (promoter clearance or escape) and undergoes a further transition to form the elongation complex, which covers only 35–40 bp, depending on the stage during elongation. The polymerase now becomes tightly bound to both the nascent transcript and the DNA template, making it very stable.

The average rate of transcript elongation by the various RNAPs is 40 nt s^{-1} . However, this rate varies dramatically among RNAP and loosely correlates with the subunit complexity of the enzyme. Thus, the simple single-subunit bacteriophage RNAPs are the most rapid of all DNA-dependent RNAPs (several hundred nt s^{-1}), bacterial RNAPs transcribe at an intermediate rate ($50\text{--}100 \text{ nt s}^{-1}$), and eukaryotic polymerases, although diversified, appear to be the slowest ($20\text{--}30 \text{ nt s}^{-1}$).

Recent studies of both prokaryotic and eukaryotic transcription have yielded an increasing appreciation of the extent to which gene regulation is accomplished during the elongation phase of transcription. Nevertheless, RNAPs are not as accurate as DNA polymerases. The difference in fidelity between RNA and DNA polymerases is apparently due to the higher robustness of the proofreading mechanism that characterizes DNA polymerases than that of RNAPs. Of course, the fidelity of DNA replication is of greater importance than that of transcription because, unlike replication errors, misincorporation during transcription does not result in permanent and inherited genetic changes.

Blocks to Transcription Elongation

Transcript elongation does not occur at a constant rate. Throughout the elongation phase, RNAP can be paused, arrested, or terminated. These are important events that underlie many regulatory mechanisms that govern gene expression. During a 'transcriptional pause', the polymerase temporarily stops RNA synthesis for a certain amount of time, after which it can resume the elongation process. Thus, pausing can be described as transcriptional hesitation. In contrast, during a 'transcriptional arrest' the polymerase stops RNA synthesis and cannot resume it without the aid of accessory proteins. Throughout both pauses and arrests, RNAP remains stably bound to the DNA template and to the nascent transcript. These features distinguish paused and arrested polymerases from those that have terminated and thus detached from the DNA. Pausing and termination are sometimes related because pausing is a prerequisite for termination (see below). However, not all pauses are termination precursors. The time it takes a stalled polymerase to resume elongation varies among pause sites from very short periods of time, which cannot be accurately measured, to several minutes. The fraction of RNAP molecules that respond to an elongation block is also variable because ternary complexes differ in their ability to recognize pausing signals. Elongation is controlled by transcription factors, such as GreA, NusA, NusG and Mfd, that affect RNAP processivity by modulating transcription pausing, arrest, termination or antitermination.

Transcriptional pause and arrest signals can be intrinsic; that is, sequences in the nascent transcript or in the DNA template whose interaction with RNAP can inhibit the progression of the ternary complex, such as RNA regions, which have the propensity to form a stable secondary structure. In addition, extrinsic factors may obstruct the progress of RNAP during transcript elongation. There are numerous examples of RNAPs from various organisms being physically blocked by DNA-binding proteins during RNA synthesis in natural and artificial systems. An example is the purine repressor, which binds well downstream from the *purB* operon transcriptional start point and blocks the polymerase during elongation (it should be noted that in many cases RNAP is able to transcribe beyond the DNA-binding proteins in its path by either displacing them or bypassing them). In addition to DNA-binding proteins, which are the most obvious obstacles for RNAP, factors that perturb the structure of DNA can also inhibit the progression of RNAP and thus interfere with transcript elongation, for instance, extreme positive or negative supercoiling, unusual DNA structures such as Z-DNA, and DNA lesions. The efficiency of such potential impediments to block RNAP from elongating depends on various local factors and on the type of the RNAP. For example, T7 RNAP can efficiently bypass gaps in the DNA template strand that are 1–5 nt, and less efficiently gaps as large as 24 nt.

Pausing appears to occur by a two-tiered mechanism. An initial rearrangement of the RNAP active site interrupts elongation and puts the enzyme in an off-line state, called the elemental pause; additional rearrangements or interactions with regulatory proteins or downstream DNA sequences can create long-lived pauses. Transcriptional pausing is involved in various regulatory mechanisms.

It plays a fundamental role in coupling transcription and translation by halting RNAP to allow a translating ribosome to catch up to polymerase. Given that most RNA exhibits significant secondary structure, even low-efficiency pausing that occurs with sufficient frequency will maintain coupling. Pause sites in the leader regions of operons regulated by attenuation are thought to halt RNAP to ensure that ribosomes are properly located to control the termination decision. The discovery of any attenuation mechanisms that are coupled with small molecule–RNA interactions (riboswitches) highlights the importance of pausing to proper regulation. Pausing also appears critical to ensure binding of elongation regulators to RNAP, for instance of RfaH to polymerase molecules paused at *ops* sites in the leader regions of RfaH-regulated operons. Furthermore, pausing plays a key role as the first step in both ρ -dependent termination and intrinsic termination of transcription (transcription termination is discussed in the section titled ‘Transcription termination’). Pausing halts RNAP at terminators until ρ factor interacts with the transcription elongation complex. Additionally, specific pause sites have been found to play important roles in the proper folding of the nascent RNA. The combined effects of pausing in maintaining transcription–translocation coupling and in facilitating ρ -dependent termination when translation fails creates a prokaryotic version of an mRNA surveillance pathway, in which RNA damage or mutation that would lead to defective protein synthesis causes termination of transcription.

Although transcriptional arrest has been characterized *in vitro* and the evidence for its occurrence in the cell is only circumstantial, it is also believed to be implicated in the regulation of many genes. These predictions are based on the recognition that if an arrest occurs within the coding region of a gene, the arrested complex would block subsequently initiated RNAPs, thereby effectively repressing RNA synthesis from the affected gene.

Transcript Cleavage during Elongation

When RNAP encounters a roadblock during elongation, it backtracks and the 3′-end of the nascent RNA is cleaved to generate a new 3′-terminus. Transcript cleavage serves to rescue RNAPs that are arrested during elongation and gives the enzyme a second chance to transcribe over the roadblock and resume elongation. Following the cleavage, RNAP can correctly resynthesize the discarded RNA segment and continue with the elongation. The cleavage reaction involves accessory proteins in addition to RNAP. In *E. coli*, the GreA and GreB proteins serve as cleavage-stimulatory factors. GreA and GreB also affect the size of the released 3′-fragment. GreA-induced hydrolysis generates mostly di- and trinucleotides, while GreB-induced hydrolysis generates fragments of up to 18 nt long. GreA can only prevent transcription arrest, whereas GreB can reactivate prearrested transcription complexes as well.

Besides antipausing and antiarresting function, the factor-induced endonucleolytic reaction may enhance transcription fidelity by inducing the excision of misincorporated nucleotides, and by facilitating transition of RNAP from the initiation to the elongation stage of transcription. Molecular models for the mechanism of Gre proteins action were recently proposed based on biochemical, mutational, and structural analyses. Other factors, such as NusA, can regulate the cleavage properties induced by GreA and GreB. NusA is a multifunctional transcription factor that may elicit opposite effects on transcription elongation and termination. Its activity is discussed in the section titled ‘Transcription termination’.

The Inchworm Model for Transcription Elongation

The old-fashioned view of the elongation process as a smooth forward motion during which RNAP moves 1 bp along the DNA template for every base added to the newly synthesized RNA chain might still hold for some regions of DNA. However, evidence has accumulated for a different type of movement of the polymerase during elongation. Thus, a new model for RNAP translocation has evolved: the ‘inchworm model’. This model describes the movement of RNAP on the DNA template in a discontinuous inchworm-like fashion. The model predicts that the process of RNA chain elongation is a cyclic process that consists of discrete translocation cycles. Each cycle involves the steady compression of the RNAP on the DNA template followed by a sudden expansion. According to this model, the upstream (back) boundary of the enzyme moves steadily during elongation, as the RNA chain is extended. However, the downstream (front) boundary of the enzyme does not move while several nucleotides are added; it then ‘jumps’, that is, it moves 7–8 bp along the DNA. At the beginning of each cycle, RNAP stretches across ~35 nt of template DNA; it gradually compresses from the back end till it covers only ~27 nt; it then releases from the front end and stretches again to cover ~35 nt. As the RNAP compresses, the nascent RNA chain of the complex becomes longer and the single-stranded transcription bubble enlarges as well. The internal tension that these changes probably create in the enzyme is released when the front end expands discontinuously.

The inchworm model for transcription elongation postulates that RNAP binds to the DNA template at two separate sites, one downstream in the direction of transcription and one upstream, which can move independently of each other. This permits the polymerase to move in an inchworm-like manner, so one DNA-binding site on the polymerase remains fixed to the DNA, whereas the other moves along the DNA. There is now both direct and indirect evidence that validate this assumption. The downstream DNA-binding site in the *E. coli* polymerase was found to be double-strand-specific, whereas the upstream is single-strand-specific and interacts with the template strand. The model also assumes that the catalytic site of RNAP is linked to the movement of the upstream DNA site, but can move independently of the downstream DNA-binding site. The inchworm model also makes predictions about the existence of more than one RNA-binding site on the ternary complex. It has been shown that nascent RNAs interact with at least three sites on the *E. coli* polymerase, two on the β -subunit, and one on the β' -subunit. It is believed that together the DNA and RNA sites account for the remarkable stability and flexibility of ternary complexes. However, the precise size, placement, and strand specificity of these nucleic acid-binding sites are currently being elucidated.

Transcriptional Slippage

RNAP usually synthesizes RNA transcripts that are precisely complementary to the DNA template. However, in rare circumstances, RNAP can undergo transcriptional slippage that results in the synthesis of a transcript that is either longer or shorter than the sequence encoded by the DNA template. Such a slippage appears to occur when the polymerase transcribes homopolymeric runs. It has been proposed that the generation of transcripts that are shorter than the encoding template is due to translocation of RNAP without the incorporation of nucleotides, whereas the longer products are due to RNAP-incorporating nucleotides without translocation. Transcriptional slippage can occur during both the initiation and the elongation phases. However, the minimal length of the consecutive template nucleotides that can promote slippage in the two phases is different. During initiation, homopolymeric runs as short as 2 or 3 nt can be reiteratively transcribed by RNAP. During elongation, RNAP tends to slip only on longer runs, but the precise requirements have not been elucidated. In one case, slippage by the *E. coli* RNAP during elongation was reported to require runs of at least 10 dA or dT nucleotides, whereas runs of dG at the same length did not result in slippage. In some cases, the ability to slip seems to require a transcriptional pause in addition to the homopolymeric run. Transcriptional slippage is sometimes an important means of regulating transcription. It has been reported to play an important role in the regulation of transcription initiation at several bacterial operons, for example, *pyrBI*.

Implications of DNA Topology on Transcription Elongation

Because DNA has a helical secondary structure, a rotation about its axis is necessary to accomplish transcription elongation. This requires either that the entire transcription complex rotates about the DNA or that the DNA itself rotates about its helical axis. Under conditions in which the RNAP rotation is constrained, for example, due to the presence of ribosomes attached to the nascent RNA chain (which is often the case in bacteria), the DNA will rotate through the enzyme. Consequently, the process of transcription will tend to generate positive supercoils in the DNA ahead of the advancing RNAP and negative supercoils behind it. Excessive torsional stress in the DNA will arise if the DNA is anchored at various points (as is the case for circular DNA, such as the bacterial chromosome) or from the movement of RNAP in opposite directions along the DNA. DNA topoisomerases are the natural candidates to remove this tension. It was suggested that gyrase, which can relieve positive supercoils, and topoisomerase I, which removes negative supercoils, amend the situation in front of and behind the RNAP, respectively. This model is supported by the finding that when the activities of gyrase and topoisomerase I are inhibited or otherwise defective, transcription causes major changes in DNA supercoiling. A possible implication of this is that transcription, in addition to having a significant effect on the local structure of DNA, is responsible for generating a significant proportion of supercoiling that occurs in the cell.

Implications of DNA Replication and RNA Polymerase backtracking on Transcription Elongation

To prevent collision between the transcribing RNAP and the replicating DNA polymerase, transcription regulation is carefully coordinated with DNA replication and chromosome segregation. In *E. coli* and in other bacteria and bacteriophages, heavily transcribed genes are oriented such that replication and transcription occur in the same direction. Despite this arrangement, because DNA replication occurs 10–20 times faster than transcription, RNAP and DNA polymerases do collide. Although the outcome of such an encounter is hard to predict, in several instances the replication-transcription conflict was shown to result in genome instability, leading to formation of chromosomal deletions and rearrangements. Importantly, such an encounter often results in RNAP backtracking, which involves sliding of RNAP along the DNA and RNA within the transcription bubble and stalling of the elongation complex. In addition to RNAP backtracking, transcription-replication collision also produces DNA lesions, which by themselves act as factors promoting elongation stalling. To deal with such conflicts, bacteria have evolved molecular machineries that cooperatively act at the collision site in order to resume DNA replication and transcription elongation. In a process termed 'transcription-coupled repair' (TCR), certain transcription-associated proteins recruit DNA repair factors to the conflict site and correct the mistakes that have been made in the DNA. An important protein that orchestrates TCR is the DNA translocase protein, Mfd. When RNAP stalls at a DNA lesion, the nucleotide excision repair (NER) proteins, which are necessary for repairing the lesion, cannot access the site due to the occupancy of the stalled RNAP. Under such conditions, Mfd binds to the stalled elongation complex by interacting with the β subunit of RNAP and dislodges the stalled complex by pushing it forward i.e., reverse backtracking. It then recruits UvrA to the DNA lesion site and, following repair by the NER system, elongation of the stalled transcription complex is resumed.

In *E. coli*, replication-transcription conflicts are counteracted also by other transcription elongation factors, including DksA, GreA and GreB, which are involved in modulation of RNAP backtracking. Furthermore, co-transcriptional translation, i.e., simultaneous translation of a nascent transcript, was suggested to regulate the rate of transcription elongation by preventing backtracking of RNAP. This notion is supported by the finding that NusG physically links the transcribing RNAP to the translating ribosome, and this coupling was observed to have an effect on transcription elongation and prevention of backtracking. Finally, a recent study identified UvrD, a member of the NER system, as a transcription elongation factor that physically binds to RNAP, thus promoting RNAP backtracking under conditions of replication-transcription collision. In a process independent of Mfd, UvrD was found to induce RNAP backtracking on stalled elongation complexes, using its helicase activity. By inducing backtracking, UvrD exposes the DNA lesion site to repair, which is necessary for resuming elongation of the stalled RNAP. The presence of multiple mechanisms that

function to relieve the arrested elongation complex suggests that transcription stalling, RNAP backtracking and replication-transcription collisions are unavoidable processes, which need to be rectified for efficient transcription.

In contrast to *E. coli*, in which there is evidence suggesting that the replication fork can displace the elongation complex, in bacteriophage T4, the movement of the replication apparatus does not seem to disrupt the elongation complexes, regardless of the direction of their motion relative to the replication fork. Interestingly, when direct collisions occur between the DNA and RNAPs of T4, the RNAP switches from the original DNA template strand to the newly synthesized daughter strand. The mechanism that allows the strand exchange without the dissociation of the elongation complex is not known, but probably relies on the various contacts with the DNA and RNA. Whatever the mechanism, the cell needs to coordinate the replication and transcription processes carefully.

Transcription Termination

Transcriptional elongation is highly processive and can lead to the production of RNA transcripts that are thousands of nucleotides long. The processivity is due to the high stability of the complex between the RNAP and the nucleic acids during elongation. It is this stability that necessitates the involvement of specific signals and factors to implement termination of transcription. To enable efficient termination, the termination signals or factors should cause drastic alterations of the interactions that are responsible for the stable elongation. At termination, RNAP stops adding nucleotides to the RNA chain, all the hydrogen bonds that hold the RNA–DNA hybrid together break leading to the release of the transcript, the DNA duplex reforms, and the enzyme dissociates from the DNA template. The sequence of these events is still not clear because attempts to determine whether the release of the RNAP is simultaneous with the transcript release or occurs subsequently have given ambiguous results. Once the transcript is released from the complex, it is unable to reattach in a way that allows transcriptional elongation to resume. Therefore, the transcript release is the commitment step that makes the termination process irreversible. On one hand, this mechanism ensures the termination at the end of genes and prevents the expression of adjacent distinct genetic units; on the other hand, this mechanism provides an opportunity to control gene expression.

The exact point at which termination of an RNA molecule occurs in the living cell is difficult to define. The 3′-end of an RNA transcript looks the same whether it is generated by termination or by cleavage of the primary transcript. Therefore, the best identification of termination sites is provided by systems in which RNAP terminates *in vitro*. An authentic 3′-end can be identified when the same end is generated *in vitro* and *in vivo*. In *E. coli*, two types of terminators were discovered, intrinsic terminators that do not require ancillary proteins and terminators that require the involvement of termination factors.

Intrinsic Terminators

Intrinsic terminators are sites at which core polymerase can terminate transcription *in vitro* in the absence of any other factor. The best characterized intrinsic terminators are the ones recognized by *E. coli* RNAP. Intrinsic terminators are characterized by a GC-rich sequence with an interrupted dyad symmetry followed by a run of about 6–8 dA residues on the template strand.

The transcription of the GC-rich sequence with the interrupted inverted repeats will give rise to an RNA segment that has the potential to fold into a stable stem-and-loop secondary structure (sometimes described as a hairpin structure). There is much indirect evidence that this structure is indeed formed in the nascent RNA. For example, mutations that interrupt the pairing in the stem part decrease the efficiency of termination, and compensatory mutations that restore the pairing recover the efficiency. There is also a strong correlation between the predicted stability of the structure and the termination efficiency. DNA oligonucleotides that are complementary to one arm of the stem in the stem-loop structure effectively reduce the efficiency of termination, presumably by annealing to the RNA sequence, and thus prevent the RNA from folding into the stem-loop structure. The sequence of the loop in the stem-loop structure also influences the stability of the RNA secondary structure, but the rules for contributing to loop stability have not been fully elucidated. How does the stem-loop structure contribute to termination? It is suggested that the formation of this structure in the newly synthesized RNA sequence, which is still in contact with the polymerase, causes the polymerase to pause, and thus destabilizes the ternary complex.

The other structural feature of an intrinsic terminator, the run of the dA residues (which is sometimes interrupted) in the template strand, is located at the very end of the transcription unit. The transcription of this sequence will generate a run of rU residues at the 3′-end of the RNA transcript. The hybrid between the dA and the rU residues is significantly less stable than most other hybrids, due to weak base-pairing, and it thus requires the least energy to break the association between the strands. This poor base-pairing is assumed to unwind the DNA–RNA hybrid and destabilize the interaction of the nucleic acids with the paused polymerase. The importance of the dA run has been established by mutational analysis. The importance of the length of the dA stretch was confirmed by introducing deletions that shortened this element; although the polymerase could still pause at the stem-loop, it no longer terminated. Interestingly, the actual termination can occur at any one of several positions toward the end of the dA run.

The DNA sequence within 30 bp downstream to the transcription stop point, which does not reveal an obvious consensus sequence, is also important for termination in certain cases. For example, changes in the sequence 3–5 bp downstream to the stop point of T7 early-gene terminator can reduce the efficiency of termination from 65 to 10%. Although these sequences are not transcribed, they are near or within the contact point between the RNAP and the DNA in the transcription complex. The way these

sequences can affect transcription is by influencing the unwinding of the DNA or the progression of the polymerase along the DNA. Alternatively, the stability of the binding of the polymerase could vary depending on the sequence at the contact points.

Recently, a distinct class of branched intrinsic terminators was identified. Anti-Q is a small RNA encoded from a plasmid of *Enterococcus faecalis* that confers antibiotic resistance. Relative to the larger transcript that is transcribed from the same operon, anti-Q is produced via factor-independent termination. Unlike the known terminator structures, which are typified by a G + C stem loop followed by a poly-uridine tract, the terminator sequence of anti-Q folds into an unusual branched structure with a basal stem, followed by a poly-uridine tract. The branched structure, which resembles a Y-shape, was found to be essential for transcription termination and for subsequent release of the RNA polymerase. Importantly, a bioinformatic search for similar sequences in bacterial genomes identified several genes with potential anti-Q-like terminator structures. Termination of at least one of the studied genes via an anti-Q-like terminator structure, albeit at a low efficiency, was experimentally validated. This newly discovered flexibility in the structure of factor-independent terminators calls for reassessment of bacterial genomes coding capacity and annotation.

Rho-Dependent Termination

The best characterized termination factor is the bacterial ρ protein. ρ is a classic termination factor in the sense that it provides a mechanism for dissociating nascent transcripts at sites that lack intrinsic terminators. Rho is essential for the survival of most bacteria, although in some prokaryotes Rho is dispensable, or absent altogether. Rho binds to the nascent RNA chain. The sequences that form a ρ -dependent terminator extend from at least 60 bp upstream to about 20 bp downstream of the actual stop point. ρ -binding sites show a highly inconsistent sequence homology and their only common feature is a relatively high cytosine content. In addition, ρ has a strong preference for sufficiently long segments of unstructured RNA (lacking base-pairing).

ρ causes RNAP to terminate preferentially at points that are natural pause sites. These pause signals often encode U-rich RNA–DNA hybrids, which have the added consequence of destabilizing the transcription elongation complex. There is no evidence that ρ affects the elongation-pausing specificity of the polymerase, but several lines of evidence point to a highly specific conformation of the elongation complex preferred by ρ . In addition to ρ being an RNA-binding protein, ρ contains an RNA–DNA helicase activity; it hydrolyzes ATP to energize the separation of an RNA–DNA hybrid termed R-loop. Recent studies have found that an essential function of Rho is to prevent R-loop formation, which are formed across the genome not only by transcription read-through, but also by antisense RNAs. In agreement with its role in R-loop prevention, Rho was found to be non-essential in cells expressing the R-loop helicase UvsW. Thus, ρ is acting primarily as an RNA-release factor. The recently solved crystal structure of ρ could explain many of its activities, although many questions pertaining to ρ -recognition sites, enzymatic activities, and interactions with the elongation complex remain obscure. The current model for ρ action is that it binds to the RNA transcript at sites that are unstructured and rich in C residues; it then translocates along the RNA until it catches up with the polymerase at sites where the enzyme pauses; ρ unwinds the RNA–DNA hybrid in the transcription bubble; termination is completed by the release of ρ and RNAP from the nucleic acids. Some ρ mutations can be suppressed by mutations in the genes that encode the β - and β' -subunits of RNAP, implying that in addition to interacting with the nascent RNA chain, ρ also interacts with the polymerase.

The lack of stringent sequence requirements for a ρ -dependent transcription terminator raises the possibility that such terminators might be fairly frequent in DNA sequences, not only at the ends of operons but also within genes. What prevents ρ from terminating within genes? Because transcription and translation are coupled in prokaryotes, the mRNA chain that emerges from the transcription complex is protected by ribosomes, probably preventing ρ from gaining access to the RNA. The phenomenon of polarity (a nonsense mutation in one gene prevents the expression of subsequent genes in the operon) can be explained by the release of ribosomes from the transcript at the nonsense-mutation site, so that ρ is free to attach to and move along the mRNA; when it catches up with RNAP, it terminates transcription, thus preventing the expression of distal parts of the transcription unit. What prevents ρ from acting on transcripts that are not translated, such as rRNAs and tRNAs? One reason seems to be the lack of ρ -binding sites on these RNAs because they are highly structured. rRNA molecules are further protected by the binding of ribosomal proteins. Another mechanism that protects rRNA operons against ρ -dependent termination relies on sequences near the start of the rRNA genes that dictate antitermination. It was suggested that this mechanism increases the rate of transcriptional elongation of rRNA operons by preventing pausing.

Auxiliary Termination Factors

Although some polymerases can spontaneously terminate transcription at intrinsic terminators, the efficiency of termination in vitro is often enhanced significantly by the presence of additional factors. It therefore seems that the DNA signals that characterize intrinsic terminators are necessary, but sometimes not sufficient. The best characterized of these auxiliary termination proteins is NusA. A less-studied factor named τ (tau) is known to enhance and modify recognition of some strong intrinsic terminators for *E. coli* RNAP. ρ -dependent termination can also be enhanced by an auxiliary factor, the NusG protein. Small RNAs were also shown to affect transcription termination via base-pairing interactions with sequences in the mRNA.

The ability of NusA to increase the efficiency of termination at some intrinsic terminators might be attributed to its capability to increase the rate of pausing at certain sites. Enhanced pausing would allow more time for the conformational change that leads to the release of the nascent transcript. Some intrinsic terminators that are predicted to form not a very stable secondary structure, such as the one in the ribosomal protein S10 operon leader, depend on NusA for their operation, and can therefore be defined as

NusA-dependent terminators. In the case of the intrinsic terminator in the attenuator region preceding the gene for the β -subunit of *E. coli* RNAP, NusA, rather than enhancing termination, reduces termination efficiency. Indeed, as mentioned before, NusA may elicit opposite effects on transcription, depending on the RNA–DNA sequence context and the presence or absence of auxiliary factors. By itself, NusA stimulates certain types of pausing and ρ -independent intrinsic transcription termination. However, NusA can induce anti-termination at ρ -dependent terminators with RNA sequences containing ‘nut’ or ‘nut’-like elements (see below). In complex with other Nus factors (NusG, NusB, NusE) or λ phage proteins N and Q, it stimulates antitermination at both ρ -dependent and ρ -independent terminators (see below). NusA antitermination function plays an important role in the expression of ribosomal genes. During transcription of many other genes, NusA-induced RNAP pausing provides a mechanism for synchronizing transcription and translation.

NusG has a minor effect on termination at some intrinsic terminators. However, it plays a significant role in the functioning of some ρ -dependent terminators. This role was deduced from the strong effect of NusG loss on the activity of some ρ -dependent terminators in vivo and from the effect of NusG on ρ termination efficiency and pattern across a terminator in a purified in vitro system. The role of NusG in ρ -dependent termination is not conclusive, but the evidence hints that NusG might increase the retention of ρ on the nascent transcript, thereby increasing its local concentration, and/or that NusG increases the rate of RNA release at termination sites. It is also possible that NusG acts directly to enhance ρ activity or indirectly by slowing the dissociation of ribosomes from the RNA, thus preventing ρ from binding to the transcript. Recent studies have shown that Rho and NusG cooperate to prevent generation of antisense RNA across the genome.

The nucleoid-associated (H-NS) family of proteins was recently found to modulate ρ -dependent termination. Genome-wide analysis of H-NS and ρ -binding sites revealed an enrichment of H-NS at sites that are prone to ρ -dependent termination. Further support for the cooperativity between H-NS and ρ was provided by their apparent genetic interaction. Interestingly, cells expressing a truncated form of H-NS, lacking its C-terminus, or YdgT, which resembles the N-terminal of H-NS, can suppress defects in ρ -dependent termination caused by mutations in *rho*. This suggests that the H-NS family of proteins cooperate with ρ in terminating transcription. A clue to how H-NS affects ρ -dependent termination is offered by its enrichment in coding regions, which suggests that H-NS acts as a roadblock for the transcribing RNAP. Thus, by slowing the elongation rate, H-NS may provide Rho with a window of time during which it can catch up with the transcribing RNAP, a requirement for ρ -dependent termination.

Two proteins that antagonize ρ -dependent transcription termination have been identified: the *Psu* protein encoded by bacteriophage T4 and *YaeO* from *E. coli*. *Psu* seems to inhibit ρ -dependent termination by slowing down the translocation of ρ along the RNA, as this protein was shown to negatively affect the ATPase activity of ρ . A model of the *YaeO*– ρ complex, which is based on the solved structure of the two proteins, proposes that *YaeO* binds to ρ , acting as a competitive inhibitor of RNA binding.

Interestingly, the presence of the σ factor in excess significantly increases the rate of RNAP recycling. Hence, the σ factor can also be considered a termination factor. This activity supports the notion that σ can remain associated with the polymerase at postinitiation steps.

Antitermination

Antitermination is used as a control mechanism in phages to regulate the progression from one stage of gene expression to the next, and in bacteria to regulate expression of some operons. Antitermination occurs when RNAP reads through a terminator into the genes lying beyond. The terminators that are bypassed can therefore be defined as conditional terminators. Antitermination is not a general mechanism that can occur in all terminators, but is, rather, dependent on the recognition of specific sites in the nucleic acids. Many mechanisms involve choosing between two alternative hairpin structures in an RNA transcript, with the decision dependent on interactions between ribosome and transcript, tRNA and transcript, or protein and transcript. In other examples, modification of the transcription elongation complex is crucial to make it bypass certain terminators.

The N protein of bacteriophage λ mediates antitermination necessary to allow RNAP to read through the terminators located at the end of the immediate early genes in order to express the delayed early genes. The recognition site needed for antitermination by N, termed *nut* (for N utilization), lies upstream from the terminator at which the action is eventually accomplished. The *nut* site consists of two sequence elements, a conserved 9-nt sequence called BoxA, which is also an antiterminator signal in the operons encoding ribosomal transcripts, and a 15-nt sequence called BoxB, which encodes an RNA that would form a short stem structure with an A-rich loop. A number of host proteins, including NusA, NusG, ribosomal protein S10 (NusE), and NusB, participate in the N-mediated antitermination process (Nus stands for N utilization substance). A model for N-mediated antitermination at ρ -dependent terminators proposes that N recognizes and binds to the BoxB stem-loop structure formed on the nascent transcript, whereas NusB and S10 bind to the BoxA sequence on the RNA. These proteins are held together through interactions with core RNAP that are stabilized by NusA and NusG. Hence, a ribonucleoprotein complex is formed at the *nut* site and stays attached to the elongating RNAP. This complex prevents RNAP from pausing, thus denying the ρ factor the opportunity to cause termination, and the polymerase continues past the terminator. N also suppresses termination at intrinsic terminators; however, NusA suffices for N to prevent termination at these sites. Other phage related to λ have different N proteins and different antitermination specificities. Each phage has a characteristic *nut* site recognized specifically by its N-like protein. All these N-like proteins seem to have the same general ability to interact with the transcription apparatus in an antitermination capacity.

The Q protein is required later in bacteriophage λ infection. It allows RNAP to read through the terminators located at the end of the immediate early genes, to express the late genes of bacteriophage λ . Q has a different mode of action than N. It recognizes and binds to a site on the DNA, called *qut*. The upstream part of *qut* lies within the λ -promoter P_R , whereas the downstream part lies at

the beginning of the transcribed region. Thus, Q antitermination is specific for RNAP molecules that have initiated at the P_R promoter. The part of *qut* that lies within the transcribed region includes a signal that causes RNAP to pause just after initiation. This pause apparently allows Q to interact with the polymerase. Once bound, the Q-modified enzyme is released from the pause and is able to read through most transcription terminators, both intrinsic and ρ -dependent. It seems that the modification of the polymerase by Q increases the overall rate of transcription elongation and permits the polymerase to hurry past the terminators. Interestingly, the pause of the polymerase early in the transcription unit, which is a prerequisite for Q-mediated antitermination, involves the binding of the σ subunit of the RNAP holoenzyme to the nontemplate strand of DNA in the transcription bubble up to 15 nt downstream from the start point of transcription. Thus, an initiation factor acts in concert with a DNA-binding termination factor to modify the elongation properties of RNAP. Once again, it is shown that σ can remain associated with the polymerase and play a role in postinitiation steps.

RNAP molecules that are engaged in transcribing the rRNA (*rnm*) operons are modified in a way that makes them bypass certain terminators within the rRNA genes. The modification is established by the recognition of a sequence signal that is nearly identical to the BoxA sequence involved in N-mediated antitermination. It has been shown that a heterodimer of NusB and S10 protein binds to the BoxA sequence on the RNA of one of the *rnm* operon. It was therefore proposed that the mechanism of transcriptional antitermination in the *rnm* operons, similar to the mechanism mediated by N, involves formation of a ribonucleoprotein complex on the BoxA complex that is carried along with the elongating polymerase. The probable purpose of this mechanism is to ensure that transcription of the rRNAs is immune from ρ action.

Some bacterial proteins regulate gene expression by binding to specific RNA sequences and alter the structure of the leader RNA to promote or prevent transcription termination. The TRAP protein from *B. subtilis* and the BglG protein from *E. coli* represent two families of proteins that promote termination and antitermination, respectively. The BglG protein, encoded by the β -glucoside utilization operon (*bgl*) in *E. coli*, prevents the termination of transcription at two intrinsic terminators. The first terminator is in the 5' untranslated leader of the *bgl* transcript and the second is in the intergenic region between the first and second genes of the operon. BglG is an RNA-binding protein that recognizes and binds to a specific sequence partially overlapping the sequence of both terminators. By binding to its RNA target site, BglG stabilizes a secondary structure, which is an alternative to the terminator structure. Thus, BglG binding to the *bgl* transcript prevents the formation of the terminators and the polymerase can read through them. BglG exerts its effect as a transcriptional antiterminator only when the expression of the operon is required, that is, when β -glucosides are present in the growth medium. The activity of BglG as an antiterminator depends on its phosphorylation state, which affects its oligomeric form. BglG-like antiterminators were shown to control the expression of sugar utilization genes in various organisms, both Gram-negative and Gram-positive.

Unlike BglG, the TRAP protein from *B. subtilis* promotes termination of *trp* operon transcription. The transcript of the leader region of the *trp* operon can fold to form mutually exclusive antiterminator and terminator structures. When the TRAP protein is activated by tryptophan, it binds to the 5' segment of the antiterminator hairpin, freeing its 3' segment to pair with the adjacent 3' RNA segment to form a terminator structure. Since the stability of the antiterminator is higher than that of the terminator, TRAP binding is required to prevent antiterminator formation. Thus, when cells have adequate levels of tryptophan, activated TRAP binds to the antiterminator region, the terminator formed, and transcription is terminated. When the level of tryptophan drops, an anti-TRAP protein is synthesized. This protein binds to tryptophan-activated TRAP and inhibits its ability to bind to *trp* leader RNA; this results in TRAP inactivation, leading to increased expression of all the genes required for tryptophan biosynthesis.

Transcriptional regulation of operons that are concerned with amino acid synthesis and utilization by ribosome-mediated transcription termination and tRNA-mediated transcription antitermination are described in a different article.

Glossary

Abortive transductant A bacterium that has acquired transduced DNA, which has not been degraded or stably integrated into the bacterial DNA. Abortive transductant DNA can be expressed, but cannot be replicated.

Generalized transduction The phage-mediated transfer of any region of bacterial DNA from one bacterium to another. Generalized transduction can be mediated by temperate or virulent phages.

Lysogen A bacterium that harbors a prophage.

Prophage A phage in lysogeny. Prophages are replicated as part of the bacterial chromosome or as a plasmid-like element.

Specialized transduction The phage-mediated transfer of regions of bacterial DNA, located adjacent to the site of prophage insertion, from one bacterium to another. Specialized transduction is mediated by temperate phages upon their incorrect excision from the chromosome when exiting the prophage state.

Temperate phage A phage that is capable of entering either the lytic or lysogenic life cycles.

Transducing particle A phage capsid that has packaged bacterial DNA and hence is proficient for transduction.

Transducing phage A phage capable of mediating transduction.

Transductant A recipient bacterium that has stably acquired the transduced DNA.

Transduction The phage-mediated transfer of bacterial DNA from one bacterium to another.

Virulent phage A phage that is able to replicate only via the lytic cycle.

Abbreviations

cos site	Cohesive end site
HFT	High-frequency transducing
HGT	Horizontal gene transfer
HT	High-transducing

Introduction

Bacteria can transfer genes vertically to daughter cells as well as by horizontal gene transfer (HGT). There are three main classes of HGT, transformation (uptake of free DNA), conjugation (DNA uptake by cell-cell contact) and transduction. Transformation and conjugation are being covered in other articles. This article will focus on transduction, which is the bacteriophage (phage)-mediated transfer of DNA from donor to recipient bacteria. Whilst studying genetic recombination in *Salmonella enterica* serovar Typhimurium in 1952, Zinder and Lederberg observed uptake and recombination of bacterial DNA that was not susceptible to DNase treatment, and that was independent of cell-cell contact. They concluded that this was due to a DNA transfer mechanism distinct from transformation and conjugation. The authors found that the temperate phage P22 was the agent responsible, and they coined the term transduction to describe this new, phage-dependent, form of gene transfer. Even though much less studied, virus-mediated transduction has also been seen to occur in methanogenic archaea. This article however will focus on transduction in bacteria.

There are two major classes of transduction, specialized transduction and generalized transduction (see the following sections). In brief, a prophage can excise incorrectly from the host bacterial chromosome, ending up also packaging some of the flanking regions of host DNA. These genetic regions can be recombined with the homologous region in the chromosome following infection of a subsequent bacterium. This process is called specialized transduction, and requires a temperate phage. In contrast, generalized transduction can be mediated by either temperate or virulent phages. During the lytic mode of phage growth, segments of the bacterial DNA can occasionally be packaged erroneously into phage heads and these particles are released during lysis, together with

[☆]*Change History:* April 2019. J.M. Bergman, P.C. Fineran, N.K. Petty and G.P.C. Salmond updated the text, figures and references.

This article is an update of P.C. Fineran, N.K. Petty, G.P.C. Salmond, Transduction: Host DNA Transfer by Bacteriophages, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 666–679.

wild type functional phages. The phage particles packed with bacterial DNA are called transducing particles and have the ability to adsorb to bacterial surface receptors and to inject their DNA. However, as they lack phage genes, they cannot go through a lytic cycle. Instead, the injected bacterial DNA might be incorporated into the recipient chromosome by homologous recombination, resulting in stable bacterial transductants. A special case of transducing particles, called “Gene Transfer Agents” are nonreplicative phage-like particles able to move bacterial genes. These are covered in a separate article.

Studies of transduction have enabled an understanding of the nature of phages, their interaction with bacteria and mechanisms of gene regulation. Generalized transduction is an important and powerful tool in bacterial genetics, being used for genetic mapping, strain construction, mutagenesis, etc. The basis and applications of this will be further discussed in the section [Transduction as a Genetic Tool](#). Transduction is also important in natural environments, for bacterial evolution and for the spread of antibiotic resistance genes. The formation of transducing particles is generally considered an accidental process. However this view might be questioned, as a phage’s capacity for transduction may benefit its bacterial host, and therefore may also benefit the phage (see section [Transduction in the Environment](#)).

Specialized Transduction

Definition and Discovery

The process of specialized transduction was first observed using *Escherichia coli* and phage lambda (λ) in 1956, and has since been shown for many other temperate phages. The fact that λ could only mediate the transfer of a limited number of *E. coli* genes gave rise to the terms “specialized” (or “restricted”) transduction. The limited gene transfer also highlights the main difference between generalized and specialized transduction; what DNA is packaged into the phage capsid and thereby can be transferred to other bacteria. In short, a specialized transducing particle arises from an incorrectly excised prophage, which packages all or parts of its own viral genome together with some of the flanking host DNA. A generalized transducer on the other hand, can package bacterial DNA without phage DNA.

Bacteriophage lambda (λ) is one of the most thoroughly studied and well understood biological entities on the planet and our understanding of many of the known gene regulation mechanisms derives from ingenious experiments using this model phage. Not surprisingly, the most complete picture of the steps involved in specialized transduction has been elucidated using λ . Therefore, λ will be discussed below to illustrate the general mechanism of specialized transduction.

Replication of Phage λ

To understand the mechanism of specialized transduction, it is also necessary to discuss the process of λ replication. As λ is a temperate phage, it is able to undergo two alternative life cycles: lytic (where phage particles are assembled and released by the lysed host cell) and lysogenic (during which the phage genome is incorporated as a prophage into the host chromosome). As mentioned, specialized transduction relies on incorrect excision of a prophage. Therefore, the life cycle of λ , with the emphasis on the lysogenic process, will be described here, and is depicted in [Fig. 1](#).

Lambda recognizes host cells via the LamB outer membrane protein and, upon binding to this receptor, injects its linear double-stranded DNA (dsDNA) into the cell. The ends of the linear dsDNA contain 12 nucleotide single-stranded overhangs. These sites at the ends are called cos (cohesive end) sites, and allow the linear dsDNA to cyclize via complementary base pairing of the cos sites. The DNA is then ligated and has thereby formed a stable circular molecule of dsDNA. By a well-characterized regulatory mechanism, the circular λ genome now “decides” whether to enter the lytic or the lysogenic life cycle. Under conditions of the lytic cycle, new phage particles are formed and released from the cell following bacterial lysis. Alternatively, by entering the lysogenic cycle, λ can integrate into the host chromosome and thus replicate as a prophage. Because λ circularizes upon injection into the bacterial cell and integration occurs at *attP* and not the cos site, site-specific recombination into the bacterial chromosome results in a different linear gene order in the prophage than in the mature capsids, as illustrated by the *int* and *xis* genes in [Fig. 1](#).

The insertion of λ into the bacterial genome requires the phage attachment site (*attP*) on the λ DNA, and the bacterial attachment site (*attB*) located between the galactose (*gal*) and biotin (*bio*) operons on the *E. coli* chromosome ([Fig. 1](#)). The site-specific recombination between *attP* and *attB* is catalyzed by the phage-encoded Int protein, a site-specific recombinase that recognizes these short and relatively dissimilar sequences, to promote recombination. Int is a member of the family of tyrosine recombinases that have an active site tyrosine residue, which forms a covalent link to the 3' phosphate after cleavage. The integration host factor (IHF) encoded by the *E. coli* chromosome is also required during integration. During the establishment of lysogeny, *int* alone is transcribed from a promoter located inside the gene neighboring *xis* (illustrated with a *green arrow* in [Fig. 1](#)).

Once λ DNA has been inserted into the chromosome, the prophage state is maintained by the *cl* repressor and the prophage can be stably propagated upon bacterial DNA replication and cell division of these λ -lysogenic bacteria. A regulatory switch from lysogeny to the lytic pathway can be triggered by factors causing cellular stress (such as UV light), and induction of the SOS response. This ultimately leads to the generation of mature phages and cell lysis. The first step in this process is the excision of the prophage and regeneration of the circular phage DNA. During the prophage state, the *attP* and *attB* sites are hybrid sequences ([Fig. 1](#)), and cannot therefore be recognized by Int alone. Because of this, an additional phage-encoded excisionase, called Xis, is required. As a response to environmental cues for excision, the *int* and *xis* genes are cotranscribed from a second promoter upstream of *xis* (illustrated with a *blue arrow* in [Fig. 1](#)), enabling equal concentrations of the two proteins. The combined action of Int and Xis

Fig. 1 The lytic and lysogenic lifecycles of phage Lambda (λ). Following binding to the bacterial LamB receptor, λ injects its dsDNA genome (depicted in black) into *Escherichia coli*. The linear λ chromosome is then circularized by the single-stranded complementary *cos*-regions at each end of the λ genome. The cyclized chromosome is then ligated to covalently close the circular structure. After this, λ can enter either the lytic or the lysogenic lifecycle. In the lytic pathway, the λ genome is replicated and λ proteins are expressed, leading to assembly of new phage particles, genome packaging, lysis of the host cell and release of the new phages. As an alternative, the λ -encoded protein Int can promote site-specific recombination between the λ *attP* site and the *E. coli* *attB* site, leading to the establishment of the λ prophage in the *E. coli* chromosome (depicted in brown). If the *E. coli* λ lysogen is subjected to cellular stress, the prophage can be induced and the λ genome is excised from the *E. coli* chromosome. This process is catalyzed by the λ proteins Int and Xis that together can recombine the hybrid *attBP* and *attPB* sites. After this excision and recyclization, the λ genome is replicated, packaged and released during lysis of the host cell.

catalyzes the site-specific recombination of the hybrid *att* sites on either side of the prophage and enables its excision, leading to the formation of the circular λ genome. Lambda then begins DNA replication to generate long concatemers of λ DNA, interspersed with double-stranded *cos* sites, as well as transcription and translation of genes needed for production of phage particles. Once phage heads are assembled, the DNA is packaged into the heads and cleaved into genome length units in a single-stranded staggered manner, regenerating each of the single-stranded *cos* site overhangs at the ends of the linear dsDNA. This process of packaging involves numerous phage and host proteins. Phage tail proteins are then added to the heads and the completed phage particles are released from the host following lysis. These can then initiate another infective cycle.

Incorrect Prophage Excision Creates Specialized Transducing Particles

Occasionally, the λ prophage recombines in a nonspecific manner (in a process called illegitimate recombination) instead of excision by the *att* site-specific Int/Xis system. The schematics of illegitimate recombination are illustrated in Fig. 2. These rare excision events (approximately 10^{-6} frequency compared to excision by Int/Xis) result in circular phage DNA molecules that also contain bacterial genes. If these circular hybrid DNA molecules are approximately the size of the λ genome and if they still contain the *cos* sites, they can be replicated, cleaved at the *cos* sites and packaged into phage capsids. These phage capsids with hybrid chromosomes are now called specialized transducing particles.

Because the *E. coli* *attB* is situated between the *gal* and the *bio* operons, and this is where the λ prophage is located, genes in these operons were the first shown to be transduced, as they flank the prophage. A number of methods were developed to use λ to transduce genes that are not normally located adjacent to *attB*. Initially, strains that contained large genetic deletions or rearrangements were utilized because they had genes other than *gal* and *bio* closer to *attB*, which enabled their excision and packaging by λ .

By another strategy, the *attB* site was deleted and λ lysogens were isolated where the prophage had inserted with reduced specificity into the genome at alternative (secondary) sites. As well as allowing the transduction of genes located near these secondary integration points, these experiments also provided information about the sequence specificity and efficiency of the Int protein. Finally, λ can be engineered to contain transposons. If the same transposon is used to mutagenize the bacterial host, the transposon-containing λ can be inserted as a prophage at the bacterial transposon sites, by homologous recombination. Using this technique it is theoretically possible to insert λ in any nonessential gene in the *E. coli* genome. The flanking bacterial genes can be excised together with the prophage by illegitimate recombination. Once the specialized transducing particles have been packaged they are capable of initiating infection of a new recipient bacterium, and thereby bring the prophage-flanking genes with them.

Formation of Transductants

The dsDNA of the infecting transducing particle is injected into the new host and cyclized as described above. To be packaged into a phage head, the λ genome has a size-restriction. Because of this, specialized transducing particles usually have lost some phage genes (Fig. 2). This can have deleterious effects on λ function, especially in terms of integration and generation of new particles. For example, a *gal* transducing phage, λ dgal (the “d” means defective), which carries the *gal* genes will have lost the phage head and tail genes and, therefore, cannot undergo fully productive lytic growth, but can still lysogenize the host. Alternatively, a *bio* transducer, λ p*bio* (the “p” is for plaque forming), carries the *bio* genes but lacks the *int* and *xis* genes and subsequently is unable to become a prophage, but can replicate lytically.

For the specialized transductants to be formed, the horizontally acquired DNA must be maintained stably in the recipient cell. This can happen via one of a number of possible routes:

- *Homologous recombination* can occur between sequences common to both the donor and recipient bacterial genomes. This can provide stable transductants that have incorporated the transducing phage genome (Fig. 3A). These lineages will have two copies of the transduced DNA segment (merodiploid) and are useful for complementation analyses. Infrequently, however, a second event of recombination can occur, exchanging the host locus for the homologous transduced locus, resulting in a haploid transductant (Fig. 3A).
- *Lambda integration with the aid of a helper phage* may also be used for introduction of the transduced DNA. In this case the helper phage provides the functions missing from the specialized transducing particle, *in trans* or *in cis* via recombination (Fig. 3B). Coinfection with a wild-type λ and the transducing particle can result in recombination at sites shared by these phages, which can then integrate at *attB* via the *attP* and Int functions supplied by the helper phage. The resulting lysogens will harbor the genomes of both the transducing phage and the helper phage and are hence called double lysogens (or dilysogens). A single excision of both prophages yields a hybrid circular DNA that is replicated and packaged according to the *cos* sites, giving rise to alternate transducing and wild-type λ particles. The lysate will be a mixture of transducing particles and helper phages, where approximately half will be specialized transducing particles. The frequency of specialized transducing particles in this lysate is thereby a lot higher than in a lysate where the aberrant excision originally took place, and hence dilysogens are useful for the generation of high-frequency transducing (HFT) lysates upon prophage induction.
- *Phage λ can sometimes replicate as a plasmid* in the recipient cell. Mutation of the λ *N* gene or the host *nusA* gene causes reduced expression of the λ *O* and *P* genes, which are required for replication. Expression of these proteins at low levels allows maintenance of λ , essentially as a plasmid. Alternatively, acquisition of a plasmid origin of replication also provides λ DNA with stable replication and maintenance. Therefore, any one of these mechanisms can produce heritable transductants.

Other Specialized Transducing Phages

The λ phage has provided an excellent system for unraveling the mechanisms of specialized transduction. The model based on experiments on this phage predicts that aberrant excision of any prophage that packages its DNA based with phage-specific sequences (analogous to the λ *cos* sites) could lead to production of specialized transducing particles. Indeed, many specialized transducers have been identified, including *Pseudomonas aeruginosa* phage D3 and *Bacillus subtilis* phage SP β . Further information on the frequency of specialized transduction may be provided from comparative genomics, since it is also possible that some of the apparently degenerate prophages present in many sequenced bacterial genomes may have resulted from past events of specialized transduction.

Generalized Transduction

Unlike specialized transduction, where (normally) only genes flanking the prophage insertion site can be transduced, generalized transduction is a process whereby any section of the bacterial DNA can be transferred from one bacterium to another via a phage particle. This was first identified by Zinder and Lederberg, during studies of the *Salmonella*-infecting phage P22 in 1952. They showed that this temperate phage was able to transfer chromosomal DNA from several loci, from one strain of *Salmonella* to another. In 1955, Lennox identified phage P1 as a generalized transducing phage of *E. coli*. Early studies of P22 transduction in *Salmonella* and P1 transduction in *E. coli* have been reviewed elsewhere (see “Further Reading”). These two “model” phages have been used in extensive studies about transducing phages and the mechanisms of generalized transduction. The findings from these

Fig. 2 Formation of specialized transducing particle by aberrant prophage excision. The λ prophage (in black) can be imprecisely excised from the *E. coli* chromosome (in brown) by infrequent events of illegitimate recombination. As a result, the cyclized λ chromosome might lack some phage genes (in the case depicted; the genes for phage head and tail proteins), but instead carry some bacterial genes that were flanking the prophage (here; part of the *gal* operon). By the events represented in the figure, the formation of a *gal*-transducing λ particle is shown. This λ dgal transducing particle will be deficient in formation of new phage particles upon infection, but is capable of lysogeny and thereby transduction of the *gal* genes.

studies, as well as studies of other transducing phages, have contributed to current knowledge on generalized transduction, which is summarized below.

Properties of Generalized Transducing Phage

The known, naturally occurring generalized transducing phages are tailed phages (*Caudovirales*, including members of the *Myoviridae*, *Siphoviridae* and *Podoviridae*) and store their genomes as dsDNA. Generalized transducing phages can be either virulent or temperate and, importantly, utilize a sequential headful DNA packaging mechanism. Occasionally during DNA packaging, bacterial DNA, instead of phage DNA, is packaged in error into a structurally unaltered phage head, resulting in a transducing particle instead of a fully functional phage. For this to occur, the phage must not degrade the host DNA completely upon infection. The life cycle of a generalized transducing phage is summarized in Fig. 4.

Headful Packaging

As part of the lytic cycle of phage growth, the phage structural proteins are made. Among these, the phage capsid proteins assemble into the virion head, or prohead. The proteins forming the phage tails are assembled separately. The phage DNA is then replicated and forms concatemers of phage genomes, arranged after one another in tandem. These concatemers are usually around four

Fig. 3 Transductant formation (merodiploid and haploid) and the formation of high-frequency specialized transducing lysates. (A) Merodiploid and haploid transductants are formed by Rec-dependent recombination between a λ transducing particle and the *E. coli* genome. Here a λ dgal transducing particle is used for illustration, where *gal* represents a partial but wild-type gene sequence, and *gal*⁻ represents a complete but mutant *gal* gene sequence. The merodiploid lysogen is formed by a single event of homologous recombination between the shared *E. coli gal* sequences. Alternatively, the *gal* allele can also end up in the prophage (not shown). By a second event of recombination, the *gal*⁻ allele can be “repaired” by the *gal* allele, resulting in a haploid *gal*⁺ *E. coli* genome. (B) An *E. coli* coinfecting with a λ specialized transducing particle and a wild type λ can form a dilyso-gen. Here the example of an *E. coli gal*⁻ mutant being coinfecting with a λ dgal and a wild type λ is shown. After the phage genomes have cyclized, they can recombine at shared sequences and integrate together into the host chromosome, in a process catalyzed by Int, resulting in the illustrated dilyso-genic state. Prophage induction can lead to excision of the entire dilyso-gen, giving rise to a high-frequency transducing lysate.

genomes long, depending on the phage. This newly replicated DNA must then be packaged into the phage proheads, which for both P1 and P22 is initiated by the recognition of a specific sequence of the phage DNA, called the *pac* site. The phage terminase protein recognizes the *pac* site and the phage DNA is cleaved at or near this site. This cleaved *pac* end is bound to the large terminase subunit, which is attached to the prohead. This initiates the packaging of the linear DNA concatemer into the prohead. The DNA packaging limit is determined by the size of the phage head; hence the term “headful packaging.” Usually a little more than the size of the phage genome is packaged into each prohead. For example, the genome of P1 is 95 kb, but up to 115 kb of DNA is usually packaged per phage head. Therefore, in addition to a single copy of the phage genome, there will also be some extra phage DNA packaged, which becomes terminally redundant. Once the prohead is full, the DNA is cleaved and the cut end of the remaining concatemer is recognized by packaging proteins of the next empty prohead, which starts the next round of headful DNA packaging. By this mechanism, several proheads are filled sequentially from the remaining DNA, with 3–4 headfuls produced on average from one phage DNA concatemer. When the heads have been packaged with DNA, the tails are attached to complete the virions. After this, the host bacterium is lysed by phage-encoded lysis proteins and the newly formed phage particles are released. When they adsorb to a susceptible host bacterial cell, they will inject their DNA into the cell. Because of the terminal redundancy, the ends of the DNA can recombine, and the linear phage DNA undergoes circularization, which protects it from host cell nucleases. The next step will again be the decision between the lysogenic life cycle, with the phage DNA either inserting into the bacterial chromosome (P22) or remaining as a plasmid (P1), or the lytic life cycle and the initiation of the construction of new phage particles.

DNA Packaging in Transducing Particles

As described above, generalized transducing particles arise through a mistake in the packaging of DNA into phage heads, so that the host chromosomal or plasmid DNA is packaged into some phage heads instead of the phage DNA. How often generalized transducing particles are formed depends on the frequency of the DNA mispackaging; normally an infrequent event. Experiments with P22 showed that the transducing particles in a lysate account for approximately 2% of all phage particles in the lysate, and a new analysis of next generation sequencing data from a P1 lysate suggested that 3.8% of the P1 particles carry genomic material from the host, rather than its own phage DNA.

There are two main ways for transducing particles to arise. For P22, the phage DNA packaging apparatus is able to also recognize sequences on the bacterial DNA, which are sufficiently similar to the phage *pac*-sequences. Binding to these *pac*-like sequences, a phage head can be packed with host DNA instead of phage DNA. For P1 however, this phage seems to be able to initiate mispackaging of host bacterial DNA from nicks or ends of the DNA. Regardless of the mechanism of initial host DNA recognition, the generalized transducing particles are then filled in the same manner: by headful packaging, followed by DNA cleavage and the filling of the next phage heads from the bacterial chromosome or plasmid DNA. Just as for the packaging of phage DNA, it is the size of the phage head that determines how much host DNA can be packaged, and thereby transduced. Because of different head sizes, P22 can package and transduce approximately 44 kb (around 1% of the host genome) per transducing particle, whereas the larger P1 can transduce around 115 kb (around 2% of the host genome). The *B. subtilis* phage PBS1 has an even larger head and is capable of packaging up to 300 kb (around 8% of the host genome).

Any region of the host DNA can be packaged into a prohead in this way, as long as the DNA fulfills the required criteria (contains a *pac*-like site for packaging by P22, or is cut or nicked if packaged by P1). The frequency of transduction of different regions of the genome can however vary. Because *pac*-like sites might be unevenly distributed along the host DNA, different transduction frequency for different loci is particularly noticeable for generalized transducing particles arising from mispackaging from *pac*-like sites. For this reason, wild type P22 will transduce bacterial loci that are located close to *pac*-like sites with a higher frequency. High-transducing (HT) mutants of P22 display increased and host chromosome-wide efficiency of transduction, which appears to be due to a reduced specificity in *pac*-site recognition. Because of this, the resulting P22 HT particles can transduce different regions of the host chromosome with a similar frequency. Interestingly, the mutations responsible for the HT phenotype of P22 map to gene 3, encoding the small unit of the terminase required for *pac*-site recognition and subsequent initiation of DNA packaging. This shows that mutations affecting packaging specificity can improve and enhance the transducing ability of a phage. These observations support the model for P22 packaging host DNA at sites related to *pac*. Once the DNA has been packaged into a phage head, the only difference between a phage and a transducing particle is the origin of the DNA in the head. Since a transducing particle looks like a regular phage from the outside and is able to adsorb to a new host cell by its tail proteins, subsequent infection occurs as for a normal phage, up to the point of DNA injection into a susceptible host (Fig. 4).

Fate of Transduced DNA

Once the DNA has been injected into a new bacterium, the fate of the transduced bacterial DNA will differ from that of phage DNA. The possible outcomes are listed below and are summarized in Fig. 5.

Abortive transduction

Following DNA injection, the DNA from the majority of transducing particles (90%) will remain extrachromosomal. In this case, the linear DNA is hypothesized to be injected into the cell together with a phage-encoded protein from the prohead. This protein is believed to bind to the ends of the transduced DNA and circularizes it, thus protecting the DNA ends from host nucleases. Studies of phage P1 indicate that the injected DNA in this case is circular in the recipient bacterium, and that the circles can be disrupted by protease treatments, suggesting that one or more proteins are involved in the circularization of the transduced DNA. Genetic studies of P1 and P22 phage mutants with decreased frequencies of abortive transduction have identified phage head proteins to possibly be involved. In the case of phage P1, it has been suggested that the identified protein might also play a role in joining phage heads and tails. For phage P22, a mutation causing a decrease in abortive transduction mapped to a genetic region encoding several proteins that are injected during infection. However, the exact identity and function of these proteins are still unknown.

The circularity of the DNA prevents recombination with the recipient bacterial chromosome, but this DNA may remain stable in this way for several generations and genes that are present on the DNA can even be transcribed. However, since this DNA has no origin of replication, it is unable to replicate, and is therefore inherited by only one single daughter cell following division. It is therefore called abortively transduced DNA. Because of this, any phenotype encoded by this transduced segment of DNA will be apparent in only a small minority of the offspring, giving rise to minute transductant colonies.

Abortive transductant DNA is rarely able to recombine with the chromosome in the recipient cell. However, damage to the transduced DNA may stimulate recombination. Nicks that have formed in the circularized DNA can promote the action of the host DNA repair system, resulting in recombination. For example, it has been shown that UV irradiation of generalized transducing phage lysates achieves a higher rate of stable transductants, by stimulating recombination and by reducing superinfection killing.

Recycling of nucleotides

The DNA injected by a minority of the transducing particles will be left unprotected by the phage proteins that are involved in abortive transduction. This unprotected DNA will face either of two fates. It may be degraded by host cell nucleases into component

Fig. 4 The life cycle of a generalized transducing phage. During the lytic cycle, the phage adsorbs to the donor bacterium and injects its DNA. The phage DNA (in red) is replicated, and the DNA of the donor host (in blue) is partially degraded. Phage proteins are expressed, which leads to the assembly of new phage particles and packaging of phage DNA. Occasionally pieces of bacterial DNA can be mispackaged into a phage head. Phage tails are added to the DNA-filled phage heads and the new virion particles are released by cell lysis. Because of the occasional mispackaging, some of the released phage particles will contain host DNA, and are therefore referred to as generalized transducing particles. These transducing particles are still capable of adsorbing to and injecting their DNA into susceptible host cells (the recipients). Since no phage genes are present, the recipient cells will not be lysed. Given sufficient levels of homology, the injected donor DNA can be recombined into the recipient chromosome (in green), giving rise to a transductant cell. It is also possible for the transduced DNA to be stably maintained in the recipient cell by mechanisms other than homologous chromosomal recombination, such as the homology-independent insertion of transposons, and various mechanisms of plasmid selection.

nucleotides, for the cell to use for bacterial genome DNA repair. It has been estimated that only 8%–15% of total transduced DNA undergoes this process. The other possible fate of nonprotected transduced DNA is to become stably incorporated into the host genome, which is how transductant bacteria are formed.

Fig. 5 Possible fates of transferred DNA during generalized transduction. The injected donor DNA can undergo either of three possible fates. The vast majority (estimated to 90%) of the injected DNA will be circularized with the help of phage proteins, thereby being protected from degradation and also from recombination. However, this DNA cannot be replicated and this process is therefore called abortive transduction. Approximately 8% of the injected DNA will be degraded into single nucleotides that will be incorporated into the host chromosome. A small minority (about 2%) of injected DNA will have long (at least 500 bp) stretches of sufficient homology to the recipient genome, and can thereby be recombined into the recipient chromosome.

Chromosomal recombination

The most common way for transduced DNA to be stably incorporated, and thereby inherited, is by recombination into the host chromosome. If the recipient and donor bacterial chromosomes are sufficiently sequence related, the transduced donor DNA can be incorporated into the recipient chromosome by homologous recombination. Usually this process happens within an hour of transducing particle infection of *E. coli* and *Salmonella*. After this time any remaining transduced DNA is usually degraded to nucleotides and recycled, and recombination is unlikely to happen. Homologous recombination and the subsequent formation of stable transductants requires the bacterial Rec proteins to act on the homologous pieces of DNA and replace the equivalent DNA on the recipient chromosome by the donor DNA. This leads to expression of the genes encoded on this stretch of DNA and manifestation of any corresponding phenotypes. Since the transduced DNA is incorporated into the bacterial chromosome, it will be replicated and inherited by all daughter cells, unlike in abortive transduction. Stable recombination into the chromosome is a rare event. For transduced segments of DNA with continuous stretches of at least 500 bp homology to the host chromosome, it has been shown that only about 2% of the DNA injected by transducing particles normally undergoes homologous recombination into the recipient genome.

Transduction of plasmids

Some generalized transducing phage, but not all, are able to transduce plasmids between host bacteria. During this process, the plasmid DNA is packaged into the phage head by normal headful packaging and is injected into the new host by the transducing particle. Once intracellular, the plasmid recircularizes, replicates in the new host and becomes inherited by the daughter cells after cell division. Broad host range phages, which can adsorb to and inject their DNA into even distantly related bacteria, may not be able to successfully transduce chromosomal DNA into recipient bacteria with low genetic identity. However, these phages may still be able to transduce plasmids between genetically diverse bacteria, as this does not rely on homologous recombination and any genetic identity between donor and recipient DNA (see also [Transduction as a Genetic Tool](#)).

Development of Other Generalized Transduction Systems

Not all phages that package their DNA by the headful packaging mechanism are natural transducers. As mentioned above, the host genome must not be too highly degraded in order for it to be packaged into transducing particles. For example, the well-characterized *E. coli* phage T4 packages its DNA by the headful mechanism but is not capable of efficient transduction in its

wild-type state. However, this and other virulent phage that use the headful packaging method are obvious targets for engineering into generalized transducing phages. Phage T4 has been modified by mutagenesis of endonuclease genes, thereby preventing the degradation of host DNA upon T4 infection. This results in bacterial DNA being left sufficiently intact to allow mispackaging to occur. As T4 does not require *pac* sites in order to package its DNA, mutant T4 (i.e. T4GT7) is able to package both bacterial and phage DNA equally well, making it an extremely efficient generalized transducer.

Even the temperate phage λ , the classical model for specialized transduction, can be adapted into a generalized transducer, albeit an inefficient one. Still, the necessary adaptations are interesting from a mechanistic point of view. As discussed above, λ does not use the headful packaging mechanism, but instead cleaves the DNA concatemers at specific *cos* sites found at either end of the phage genome. To initiate headful packaging and DNA cleavage, only one *pac* site (or *pac*-like site) is needed, whereas two *cos* sites, one at either end of the DNA, are required for DNA packaging in λ . In this system, packaging is initiated by recognition of the first *cos* site. The second *cos* site is the signal to end the packaging and to cleave the DNA. As with phages dependent on *pac* sites, mispackaging of host DNA can occur if DNA sequences resembling *cos* sites are found on the bacterial chromosome. However, the chances of two *cos* sites being found on the host DNA, exactly the required length apart, are minimal. If the signal to cleave the mispackaged host DNA, the second *cos* site, is absent, a length of DNA will protrude from the prohead. This prevents the tail from binding and functioning transducing particles cannot be formed. However, it is possible to treat a lysate like this with DNase to cleave the excess DNA (which is not being protected by the prohead). After this *in vitro* treatment, the phage tails are able to spontaneously attach to the proheads, which completes the formation of the generalized transducing particles. However, even with manipulations and treatments, λ is a poor generalized transducer and is mainly used in the laboratory as a specialized transducer.

To search for novel generalized transducers for bacterial strains, a combination of experimental and bioinformatic approaches may be used. For this purpose, headful packaging phages can be enriched for, in an environmental sample, by using their reduced sensitivity to chelating agents. As an example, sodium pyrophosphate has been used to isolate transducing phages for *Streptomyces venezuelae*. As mentioned, the phage terminase protein is involved in the recognition of phage *pac* sequences, initiating the series of packaging events that result in mature phage particles. Therefore, phages with terminases that have reduced *pac*-specificity are predicted to be better transducers, as demonstrated by the observation that P22 HT gene 3 terminase mutant phage is a more efficient transducer compared to the parental P22. With increasing numbers of phage genomes being sequenced, genomic information also could be used in the searches for generalized transducers. There are efforts to use data from next generation sequencing, including the relative frequencies of reads from different genomic regions, to identify phage termini sequences and thereby determine the packaging mechanism of the phage. Using the same sequence data, it has also been shown to be possible to measure the amount of host bacterial DNA in the sample, giving an estimated frequency of transducing particles in a phage lysate. Using genome data and comparative genomics may thus help narrow the search for generalized transducers. To develop and improve generalized transducers in the future, it may be worthwhile to use both rational and randomized mutagenesis approaches to alter terminases (e.g. P22) or genes involved in host DNA degradation (e.g. T4).

Methods independent of genomics have also been devised to increase the frequency of transduction for phages that are poor transducers, or for the transduction of bacterial loci that are normally transduced at low frequencies. As already mentioned, UV irradiation of the donor lysate can increase the frequency of generalized transduction greatly as this treatment leads to the introduction of DNA breaks and by that stimulates recombination between the transduced DNA and the recipient's chromosome. Also, synthetic insertion of a phage *pac* site into the bacterial DNA will greatly increase the transduction efficiency of that region. This is particularly useful for transduction of plasmids, as these are often transduced at lower frequencies than chromosomal markers.

Phage Mu—A Special Case

The highly studied phage Mu is most known for its properties as a transposable element. However, it can also operate as a generalized transducing phage, as well as having some features of a specialized transducing phage. Packaging of Mu DNA into proheads is dependent on a *pac* site, and the DNA is packaged by the headful mechanism. When the genome of phage Mu is packaged it is flanked by host DNA; a short region of up to 150 bp at the left-hand end and a larger region of up to 3 kb on the right-hand end. Since Mu replicates by replicative transposition in the host chromosome, these flanking host sequences are variable. As for other headful packagers, Mu-transducing particles are believed to arise primarily due to the mispackaging of host DNA. However, it cannot be ruled out that at least some transduction events observed for Mu are derived from recombination with host DNA present at the right-hand end, as a version of specialized transduction. It is also possible to perform transduction using mini-Mu, a Mu derivative with the central region of the phage genome deleted, leaving only the ends intact plus the transposase A gene (essentially the Mu sequences important for transposition). If the host cell is infected with a helper Mu, the chromosomally integrated mini-Mu can be induced. It will thereby be packaged into a helper Mu-encoded prohead together with parts of the adjacent bacterial chromosome, to a total length of 39 kb of DNA. The vast majority, 90%, of the transductants that arise following infection with this mini-Mu/donor DNA transducing particle, are the result of RecA-dependent homologous recombination with the recipient DNA. The remaining 10% of the transductants result from "mini-Muduction." In this case the donor DNA has a copy of mini-Mu at each end. This Mu-host-Mu DNA can insert anywhere into the recipient DNA, effectively acting as a random insertion of a transposon. Because of this, homology between the donor and recipient DNA is not required for mini-Muduction. This allows transduction/mini-Muduction of DNA between any species of bacteria that are susceptible to Mu

infection. Mu has a relatively broad enterobacterial host range, meaning that it is able to infect and replicate in many different bacteria. This makes it a useful genetic tool, especially for bacterial strains without any other identified generalized transducing phages. Clearly, phage Mu not only functions as a transposable element, but also displays properties of both generalized and specialized transducing phage.

Variations on Transduction

Lysogenic Conversion and “Cargo” Genes

Analyses of the increasing numbers of fully sequenced bacteria (including their prophages) and free phages have revealed that many harbor nonessential genes of putative bacterial origin. Genes on prophages often give an advantage to the bacterial lysogens by the expression of toxins or virulence factors that may aid bacterial pathogenesis. Since the bacterial host is “converted” upon lysogeny, this phenomenon is called lysogenic conversion. Two classical examples are the prophage-encoded shiga toxin produced by certain pathogenic *E. coli* lysogens, and the cholera toxin expressed by *Vibrio cholerae* lysogenized by the CTX phage. There are also examples of phage-encoded gene products, of bacterial origin, that can aid virulent phages during lytic infection. As an example, many cyanophages express photosynthetic proteins during infection of cyanobacteria. These phage-encoded systems have been shown to maintain bacterial photosynthesis during phage infection. This increases biosynthesis in the infected host cell, thereby aiding phage replication. These photosystem genes are bacterial in origin, acquired by phages and then shuffled among the phages by coinfection. In some cases, these genes have been recombined back into some cyanobacteria. The generation of a bacterial recombinant following infection with a virulent phage can only arise when the infection is nonproductive and the phage failed to lyse the host cell. Therefore, it is theoretically possible to define both virulent and temperate phages that carry these “cargo” genes as a form of potential, and environmentally-important, transducing phages, since these genes may be acquired from, and maintained in, infected bacteria. It is interesting to consider how these “cargo” genes might have been acquired by the phages (e.g. by illegitimate recombination and/or incorrect prophage excision). This sort of genetic promiscuity and modularity in phage genomes illuminates the dynamic evolution of phages and their hosts, resulting in a “web of life,” rather than a “tree of life” (see also [Transduction in the Environment](#)).

Auto-Transduction

Even in bacterial populations without free phages initially, transduction can occur. In a mixed community, where one subpopulation carries prophages and one does not, the prophage-free subpopulation will be susceptible to phages released as a result of prophage excision from the other subpopulation. This can lead to lysis of the prophage-free subpopulation and the mobilization of its genes. The resulting transducing particles might then re-infect the lysogenic subpopulation and insert their DNA, which will include some genes from the competing bacterial population. Since the lysogenic subpopulation is resistant to lysis by what is effectively their own prophage, this results in the prophage-carrying subpopulation ending up with newly acquired genes, which may encode resistance to antimicrobials. Furthermore, the competing prophage-free subpopulation ends up decimated by lysis, which is a further advantage for the lysogenic population. This has been demonstrated in mixed populations of *Staphylococcus aureus*, both in vitro and in vivo in a wax moth larvae system.

Clearly, phages and prophages are constant sources of genetic mixing that often blurs the boundaries between what are considered phage and bacterial genes. When reassessed in this broader context of general phage evolution, many more phages might be considered as transducers, albeit at a very low frequency compared to the well-characterized classes of specialized and generalized transducing phage.

The Influence of CRISPR-Cas Adaptive Immunity on Generalized Transduction

Bacteria have a range of mechanisms to resist phage infection and one of these is the clustered regularly interspaced short palindromic repeat (CRISPR)-CRISPR-associate systems. These provide a sequence-specific memory of past viral invaders and, through the use of small guide CRISPR RNAs (crRNAs), they use nucleases to destroy the invading phage nucleic acids. CRISPR-Cas also limits horizontal gene transfer by impeding transformation and conjugation. Recently, it has been shown that by providing resistance against wild-type phages, CRISPR-Cas increases the success of transductants and therefore can positively influence generalized transduction. In rarer cases when spacers are acquired that match the transduced bacterial DNA (instead of the phage genome itself), gene transfer is inhibited. Generalized transduction has also been observed to mobilize the CRISPR sequences and *cas* genes and thus, can lead to the spread of phage resistance. Given the widespread distribution of CRISPR-Cas immune systems in approximately half of bacteria, these systems will likely be having a significant role in generalized transduction and the dissemination of genetic material in global ecosystems.

Transduction as a Genetic Tool

Ever since the discovery of phages, and continuously with the growing knowledge of phage biology, researchers have developed the potential for practical use of phages (and their products), to aid molecular biology and its applications in biotechnology and

synthetic biology. Examples of these tools and applications include phages as antibacterial agents (e.g. for selection of bacterial mutants in the laboratory, or as agents for biocontrol and for phage therapy), as DNA vectors for expression of particular genes in host bacteria (e.g. for transposon delivery or reporter gene expression), and as components of DNA cloning, integration, and expression systems. These cases represent just a handful of phage uses, with those related to their transducing (especially generalized) properties being covered here. In addition, the understanding of various bacterial antiphage mechanisms have been exploited for practical use (such as restriction enzymes and the CRISPR-Cas technology), which however are beyond the scope of this article.

Isolation and Characterization of Generalized Transducing Phage

In order to use a generalized transducing phage for any bacterium, the first requirement is to isolate a phage with transduction capacities, for the bacterium of interest. There is extensive evidence of the ubiquitous and vast distribution of phage in the natural environment, and estimates suggest that there are approximately 10 phages for each bacterium on Earth. To isolate phages, it is therefore a good starting point to use material from where the host bacterium was found. For enteric bacteria for example, sewage water and sludge are good sources of phages. By sampling several sources, using the target bacteria as an indicator, phages infecting many bacterial genera have been isolated. The phages are then screened for transducing ability. To do this, a phage lysate is prepared on a donor strain of the susceptible bacterium that harbors a selectable marker, for example an antibiotic resistance-encoding transposon. Transduction is then performed into a wild-type recipient (near-isogenic to the donor), selecting for the marker. Any putative transductant colonies can then be screened for, for example, by PCR if the exact genetic insertion site of the selectable marker is known. If the selectable marker is inserted in a gene encoding a known phenotype (e.g. an auxotrophy), coinheritance of the expected phenotype can be screened for directly by growth on minimal media. As a complement to the transduction of chromosomal markers, the ability to transduce plasmids can be tested. This is done much in the same way, using selectable markers, with additional screening for physical evidence of the plasmid DNA in the putative transductants, for example by PCR or restriction digestion of isolated plasmid DNA. Transduction of multiple loci is required to confirm isolation of a generalized transducing phage.

Using similar strategies, generalized transducing phages have been isolated for species and strains of many different bacterial genera, including *Bacillus*, *Caulobacter*, *Citrobacter*, *Dickeya*, *Lactobacillus*, *Myxococcus*, *Pantoea*, *Pectobacterium*, *Pseudomonas*, *Salmonella*, *Serratia*, *Staphylococcus*, *Streptococcus*, and *Streptomyces*. The isolation and use of generalized transducing phages have rendered the respective host organisms more genetically amenable, and therefore easier to study. Below, the most common uses of generalized transducing phage are discussed.

Strain Construction

To perform genetic manipulations and genetic analyses of bacteria, the ability to transduce loci using selectable markers is useful. The power of generalized transduction can be seen particularly by its use in combination with transposon mutagenesis or the localized insertion of selectable markers (by e.g. recombineering). Typically, following transposon or recombineering mutagenesis, it is necessary to confirm the presence of the insertion, which can be done by PCR analysis. However, it is also formally possible that secondary mutations may have arisen in the mutant strain during the insertion of the marker. To obtain a strain with the selectable insertion in a background free from any unwanted mutations present in the original strain, generalized transduction can be used to move the insertion of interest. Coinheritance of the marker and the associated phenotype studied confirms that the appropriate selection cassette responsible for the phenotype in question. Furthermore, with the use of a variety of selectable markers, the construction of double and multiple mutant strains by generalized transduction is comparatively facile.

Localized Mutagenesis

To examine gene function in detail it is necessary to analyze the effects of mutations, by comparing the phenotype of the mutant to that of the corresponding wild type. There is often value in studying more subtle mutations than those generated by knockout or transposon disruption, such as point mutations or small insertions or deletions. It is possible to perform localized mutagenesis by error-prone PCR of the locus of interest, followed by a strategy to recombine the mutated sequences into the bacterial chromosome. For some bacterial species it is also possible to directly introduce the desired small or large mutations by the use of lambda red-based recombineering (another phage-based cloning strategy). These are powerful and “clean” techniques, but do rely on suitable delivery (e.g. transformation and/or conjugation) systems for the organism studied. To avoid this potential problem, it is also possible to subject the bacterium to mutagenesis by UV irradiation or chemical treatments, followed by a screen for mutants. However, after a general mutagenesis, any mutants with interesting phenotypes may also contain other mutations elsewhere in the genome, complicating further analysis. If the gene of interest is located in the vicinity of a selectable marker, it can be transduced from the mutated strain into an unmutagenized background. These transductants can be selected for using the resistance marker and, by linkage, screened for the phenotype attributable to nearby mutations in the gene of interest. Similarly, a transducing lysate, prepared on a strain with a selectable marker close to the gene of interest, can itself be exposed to mutagenic agents such as hydroxylamine or nitrous acid. By this method, only the DNA packaged within the transducing particles is mutated, which means that any mutations introduced will be linked to the selectable marker.

After the transduction, and with the help of cotransduction frequency, interesting mutations can be identified (e.g. by sequencing or phenotyping), as the stretches of DNA transferred by transduction are relatively short, thereby enabling a “localized” mutagenesis.

Genetic Mapping

Genetic mapping by transduction has been used historically in *E. coli*, *Salmonella* and in other bacteria to determine the fine genetic structure of closely linked genes and mutations within genes. With the now cost-effectiveness and ease of whole genome sequencing, there is now little need for these transduction-based genetic mapping experiments. However, the basic principle of transductional mapping is the measurement of the genetic linkage of loci, which can be assessed by the cotransduction frequency. Simply, if two mutations are linked (both exist within the DNA packaged in the phage capsid), they can both be recombined into the recipient chromosome (cotransduced) at a particular frequency reflecting linkage. The linkage depends on the distance between the loci and the number of recombination events required to isolate cotransductants. Likewise, an approximate distance (in genetic base pairs) can be calculated if the linkage is measured and the size of the DNA packaged into the heads of the specific phage is known.

Plasmid Transduction

For many genetic modifications and analyses in bacteria, it is necessary to introduce plasmids into recipient cells. For plasmid transfer, conjugation and transformation are usually the systems of choice. However, phage-mediated plasmid transduction can also be useful, especially for bacterial strains that have no conjugal plasmids or that have poor transformation efficiency. It can also be efficient in practical terms, as one lysate can be used to transduce the same plasmid into several recipient strains, without the need to prepare competent cells. Many generalized transducing phages are proficient in plasmid transduction. However, the efficiency varies depending on the phage and on the plasmid to be transduced. The currently accepted model is that long stretches of double-stranded plasmid DNA, formed by rolling circle replication, can be accidentally packaged into the phage proheads. After injection of the plasmid DNA into the new host, the recipient bacterium uses homologous recombination to regenerate the circular plasmid. For wild-type phage P22 to efficiently transduce pBR322, it is necessary to first introduce a *pac* sequence to the plasmid. If no *pac* sequences are present on the plasmid, pBR322 requires cloned P22 DNA sequences for efficient transduction by wild-type P22. For this, an initial homologous recombination step between P22 and the plasmid in the donor is required prior to transduction into the recipient. The dramatic increase in transduction efficiency, seen when a portion of phage DNA is cloned into plasmids, has also been observed for other bacteria and their phages, including species of *Bacillus*, *Lactobacillus*, *Staphylococcus*, and *Streptomyces*. A commonly used P22 HT derivative on the other hand, which has a reduced packaging specificity, can transduce pBR322 without any added *pac* sequences.

The plasmid transduction mechanism has also been analyzed for a T4 phage modified to be proficient in generalized transduction (see [Generalized Transduction](#)). In order to transduce pBR322, this modified T4 packages plasmid multimers equivalent of 38 monomers. To establish in the recipient host, the plasmids are separated by homologous recombination. Phage P1 is able to package plasmids that contain a P1 *inc* site. Because P1 has a broad host range (see below), it can transduce packaged plasmids into a variety of strains.

Intergeneric Gene Transfer

Some phage–host receptor interactions are highly specific, allowing a phage to only recognize a single strain of a given bacterial species. Other phages have broad host ranges, with P1 and Mu being examples. There are obvious benefits of isolating a broad host range transducing phage, where it may enable transduction within and between multiple bacterial isolates. Phage P1 has a genetic region that, when inverted, can switch expression between two alternative tail fiber proteins, a major determinant in phage–host interactions and specificity. Even though P1 is commonly used as an *E. coli* phage, depending on what tail fiber form is expressed, it can adsorb to, and replicate in, strains of *Citrobacter*, *Enterobacter*, *E. coli*, *Pectobacterium*, *Klebsiella*, *Pseudomonas*, and *Salmonella*. P1 is also able to inject its DNA into strains of *Agrobacterium*, *Flavobacterium*, *Myxococcus*, and *Vibrio* but cannot produce phage progeny in these hosts. Plasmids have been introduced into *Myxococcus* by P1 transduction, where they are unable to replicate (unless also carrying a *Myxococcus* plasmid origin of replication). The fact that the host range of P1 for adsorption is broader than the range of species where an *E. coli* plasmid origin is functional for replication is the basis of a suicide vector delivery system that is used for transposon mutagenesis and targeted gene disruptions in these bacteria.

Phage P1 has also been used to perform intergeneric gene transfers between *E. coli* and *Salmonella*. Historically, some researchers used transduction efficiency as an approximate indicator of the level of DNA homology between donor and recipient. However, due to the large genomic differences between these genera and because long stretches of near-identical sequence are needed for efficient homologous recombination, these intergeneric transductions are often unsuccessful. The ribosomal RNA loci (*rnm*) are genomic regions where such long stretches of homology can be found. Therefore, analysis of intergeneric transductants frequently showed that recombination occurred at these conserved loci, often resulting in large genome alterations. It is now known that the recipient’s methyl-directed mismatch repair system is responsible for some of the stringency of recombination and, for that reason, mismatch repair mutants are more efficient recipients of donor DNA from other genera. Because of the inefficiency and possible off-target effects, intergeneric transduction in a laboratory setting is not widely used outside of *E. coli* and *Salmonella*. However, intergeneric

transduction does have important roles in the ecology and evolution of bacteria in their natural environments, something further covered in the section [Transduction in the Environment](#).

Lambda as a DNA Delivery Vehicle

As previously discussed in this article, phage lambda is an efficient specialized transducer. It has also been developed to function as an efficient tool for the introduction of DNA into host cells. Methods developed include the packaging and transduction of cosmids and transposons by λ into target cells. Cosmids are plasmid cloning vectors that contain λ *cos* sites (giving them their name). By in vitro ligation of large chromosomal DNA fragments (up to 47 kb) into cosmids, genomic libraries can be generated, which are useful for studies of complementation and overexpression, for example. The cosmids are packaged into λ capsids in vitro, by the recognition of, and cleavage at, the consecutive *cos* sites. Phage tails are then attached, making the completed particles able to transduce the cosmids into a suitable recipient. In the recipient cell the cosmid is replicated by virtue of a plasmid origin of replication. If these cells are infected with λ , the cosmids will be further packaged in vivo, which bulks up a lysate of λ particles harboring the cosmid library.

By a similar mechanism, λ particles modified to also carry a transposon (e.g. Tn5, Tn10, Tn*phoA* or Tn*blaM*) can be used to deliver the transposon into a target bacterium. The resistance encoded on the transposon can be used to screen for mutagenesis events by transposition. For the use of this method in *E. coli*, λ replication is inhibited by amber mutations in the phage morphogenesis genes, whereas in some other genera (see below) wild-type λ is unable to replicate and can therefore be used for transposon delivery. Compared to plasmid-based mutagenesis procedures, aided by conjugation, λ -based systems are faster and have no requirement for counterselection of donor bacteria.

Lambda requires its outer membrane receptor, the maltose transporter protein LamB, for adsorption to the bacterial surface, something that originally restricted its host range and use as a genetic tool. However, by expressing the *E. coli lamB* gene from a plasmid in other Gram-negative bacteria, a wider range of hosts for λ adsorption and DNA injection has been generated. Lambda is able to infect bacteria that are capable of expressing, transporting and assembling the LamB protein in the outer membrane. The expression in *trans* of *E. coli lamB* has enabled λ to infect several strains of various genera, including *Agrobacterium*, *Pectobacterium*, *Klebsiella*, *Mesorhizobium*, *Pseudomonas*, *Salmonella*, *Serratia*, *Vibrio* and *Yersinia*. This makes the delivery of cosmids and transposons relatively straightforward in these systems, without lytic replication of λ . Interestingly, it is also possible to extend the λ host range so that λ virions can be taken up by certain eukaryotic cells, in culture as well as by antigen-presenting cells in vivo. This makes it possible to deliver cosmids and other vectors into eukaryotic cells for expression studies and vaccine delivery.

Transduction in the Environment

By comparative genomics analyses of data from the increasing numbers of sequenced bacterial genomes, it is now clear that horizontal gene transfer (HGT) accounts for a large degree of genetic diversity found within bacterial species. Phages are believed to be the most abundant biological entities on Earth, with estimates of 10^{31} phages on the planet, 10 times more than the number of bacteria. It has been estimated that the number of transduction events per year is 10^{14} in the Tampa Bay Estuary and 10^{13} in the Mediterranean Sea, demonstrating how important phage-mediated transduction might be for HGT in natural environments. Indeed, nearly all sequenced bacteria have prophages and prophage-like elements in their genomes, and these regions are often associated with adjacent horizontally acquired regions and the previously mentioned “cargo” genes of bacterial origin. Some of these phage-transferred regions encode bacterial virulence factors that can convert the host into a pathogenic strain, in the process of lysogenic conversion. For example, it is well known that the cholera toxin is encoded on a phage, CTX Φ , and infection of a nonpathogenic *Vibrio cholerae* strain with this phage can render it virulent, increasing the spread and fitness of the bacterium. Additionally, a generalized transducing phage has been shown to transduce the *Vibrio* pathogenicity island, encoding the receptor for the CTX Φ , the toxin-coregulated pilus. This allows CTX Φ to adsorb to and infect strains that normally are resistant to this phage, illustrating how HGT promoted by phage transduction plays an important role in forming the genetic diversity that is key to evolution.

Since transduction frequently relies on homologous recombination between highly related sequences, it has been difficult to determine its exact impact on bacterial genomes. With the recent advances in analyses of whole genome information, there are now a number of softwares available for comparing closely related bacterial strains, and to identify recombination events that have occurred between them. However, since recombination can result from either of the mechanisms for horizontal gene transfer, the specific importance of transduction in bacterial evolution is mainly inferred from a combination of laboratory experiments, an understanding of the global abundance of phages, and the detection of transduction in the natural environment. Some examples of this are described below.

Several studies have demonstrated that transduction of both chromosomal and plasmid DNA can occur in a variety of natural environments. Transduction of both plasmid and chromosomal markers between strains of *P. aeruginosa* has been shown in freshwater environments, as well as between bacteria on leaf surfaces, even when the donor and recipient were originally on different plants. Phages with broad host ranges have been shown to transduce plasmids among diverse bacteria in natural populations of both fresh and marine water environments. The term “silent transfer” has been suggested to describe the

phenomenon where a phage is able to transduce chromosomal or plasmid genetic information from a donor to a recipient, but is unable to plaque on the recipient. This has been seen for example in phages capable of a variant of generalized transduction of *S. aureus* pathogenicity islands (SaPIs) to other nonaureus *Staphylococcus* strains as well as to *Listeria monocytogenes*, where the phages were only seen to form plaques on *S. aureus*. The transduction of pathogenicity islands into *L. monocytogenes* could also take place in raw milk, environmentally and economically important as both *S. aureus* and *L. monocytogenes* can cause bovine mastitis. It is known that SaPIs and other “phage-inducible chromosomal islands” (PICIs) can be transferred between bacterial strains and sometimes across species barriers, by the exploitation of certain temperate helper phages. PICIs can be induced by the presence of active phages, leading to the PICI DNA being excised, replicated and packaged into phage capsids encoded by the active “helper” phage. After host cell lysis and virion release, the PICIs can be transferred with high frequencies to new hosts, much like in the case of generalized transduction. Pathogenicity islands like this often encode genes that are nonessential for PICI transfer, but that may increase the fitness of the host; such as toxins, iron transport proteins, biofilm-associated proteins and antibiotic resistance. These examples therefore highlight that transduction in the environment might directly influence human and animal health.

A recent study showed that infection and lysis by phages also could promote plasmid spread by transformation, in addition to by transduction. So-called “superspreader” phages were shown to lack genes encoding hydrolytic endonucleases, resulting in them not degrading host cell DNA during the infection. After cell lysis, naturally competent neighboring bacteria could take up the released plasmids. By this mechanism, phages are hypothesized to promote the spread of plasmids to bacteria beyond their host range, adding to the intergeneric transfer of genetic material. Instead, the host range of the released plasmids and the occurrence of naturally competent bacteria would be the limiting factors for this version of phage-promoted horizontal gene transfer.

Transduction of Antibiotic Resistance Genes

Antibiotic resistant bacteria are an increasing problem, today causing approximately 700,000 deaths per year globally, something that has been projected to increase to 10 million deaths per year in 2050. Genes for antimicrobial resistance can be spread between bacterial strains and over species borders, on plasmids and as chromosomal cassettes. Some of this spread is due to conjugation of mobilizable plasmids, but recently the importance of transduction as a driving force for the spread of antibiotic resistance has gained attention.

For the clinically relevant species *S. aureus*, phage-mediated transduction has been suggested as the main contributor to horizontal transfer of resistance genes. Prophages are very common in populations of *S. aureus*, with cells typically harboring one to four prophages. Subinhibitory concentrations of some classes of antibiotics can induce the bacterial SOS response and thus trigger the release of prophages (which in turn might trigger the mobilization of PICIs) and increase the rate of transduction within the community. Such subinhibitory concentrations of antibiotics could be found in less accessible parts of the human body, as well as in aquatic environments. Transduction of plasmids, encoding resistance to β -lactam antibiotics and to tetracycline, has under laboratory conditions been detected at high frequencies in a methicillin resistant *S. aureus* (MRSA) strain, leaving the strain resistant to multiple drugs.

Similarly, clinical strains of the opportunistic pathogen *Enterococcus faecalis* frequently carry prophages that can be activated and isolated. These phages are capable of transducing chromosomal markers and plasmids between different strains of *E. faecalis*. At least one lytic phage isolated from natural environments has been reported to be capable of transducing antibiotic resistance between different species of *Enterococcus*, including *E. faecium*, a species termed “highly important” by the World Health Organisation.

A more sequence-based approach showed that the metagenome of the fecal phage population in antibiotic-treated mice showed elevated resistance-coding genes, compared to the non-treated control. Naïve bacteria exposed to the phage population from the treated mice were also shown to acquire an increased frequency of resistance to the relevant antibiotic, compared to naïve bacteria exposed to phages of untreated mice. These experiments suggest that not only are resistant gut bacteria selected for upon exposure to antibiotics, but also the fraction of phage-carried genes encoding resistance is increased. Hence the resistance genes are both selected for as well as mobilized during the course of antibiotic treatment.

Many phages are stable and resistant to degradation in the environment, particularly in comparison to naked DNA. Therefore, transducing particles are a comparatively stable reservoir for bacterial DNA. Given these observations, and considering the vast global abundance of phages, it seems possible that phage-mediated transduction events in the environment are likely to be a major force driving HGT and adaptive evolution of bacteria.

Conclusions

The phage-mediated transfer of bacterial DNA between donor and recipient cells is called transduction. This is a form of horizontal gene transfer with implications for bacterial evolution in the natural environment. Studies of transduction have also furthered our knowledge of phage genetics and the molecular biology of phages and their hosts, as well as providing the basis for extremely useful laboratory tools. The current understanding of the molecular mechanisms of transduction has been driven by studies of a small number of “model” phage–host systems. With advances in molecular biological techniques (many of which are themselves derived from the products of phage research), it is important not to forget the power of simple genetic techniques that exploit phages. Indeed, development of a generalized transducer is still an extremely useful tool for genetic analysis of any bacterial strain. A recent

stimulation in phage research and the birth of the “-omics era” has provided major advances in knowledge of the genomes, evolution, ecology, and diversity of phages. It is anticipated that the recent rejuvenation in phage biology research will continue to further our appreciation and understanding of transduction as a tool for bacterial geneticists, the direct impacts of transduction on infections and human health, and transduction as an important evolutionary force in the adaptation of phage and their bacterial hosts.

Glossary

Ribosome A molecular machine composed of multiple RNAs (ribosomal RNAs) and proteins that consists of two subunits, the small and large subunits each of which catalyze one of the two enzymatic functions of the ribosome: decoding in the small subunit and peptide synthesis in the large subunit.

Scanning The most common mechanism of translational initiation in eukarya in which a pre-initiation complex of the small ribosomal subunit bound to the initiator tRNA and translation factors binds to the 5' end of the mRNA and moves in a 5' to 3' direction until it encounters an AUG initiation codon, where it initiates translation.

Internal initiation Initiation by binding to a site in the middle of an mRNA molecule; the common mechanism of initiation in bacteria and archaea but an alternative mode in eukarya requiring specialized mRNA sequences.

Translational repression Regulation of gene expression by blocking translation of an mRNA, which commonly involves binding of a protein factor to a site overlapping or upstream of an initiation site.

Translational coupling A mechanism of translational initiation common in bacteria in which a ribosome terminates translation and reinitiates translation at a nearby initiation codon.

Recoding A non-canonical translation event involving readthrough of a nonsense codon, frameshifting or bypassing of an mRNA segment during translation elongation.

StopGo A mechanism that occurs at sequences encoding proline-glycine-proline where translation terminates at the glycine codon, with release of the protein product, and then immediately reinitiates at the adjacent proline codon to continue and produce a second protein in approximately equimolar amounts.

Introduction

A molecular machine governs the process of transfer of genetic information from nucleic acids to proteins, termed translation. This machine, the ribosome, is a ribonucleoprotein complex composed of several RNA molecules and several dozen associated proteins. The ribosome choreographs the movements of a large assembly of other proteins and RNA molecules using an RNA template, the messenger RNA (mRNA), as a guide for the order of insertion of amino acids into a growing polypeptide chain. The process is complex and living cells depend absolutely on its speed and accuracy. Control mechanisms have evolved that manipulate the process of translation to modulate the production of specific protein products, or of generic classes of proteins.

Translational control of gene expression falls into here are two general categories: regulating the amount of protein expressed from a particular gene, or regulating the structure of the protein product. The first has to do with the speed of translation. Gene output responds to changes in either the rate that mRNAs are recruited to the ribosome (regulation of initiation) or the rate of completion of nascent polypeptide chains (regulation of elongation). Translational control may act globally, for example by activating or inactivating accessory proteins (translation factors) required for efficient translation, or locally, by stimulating or inhibiting translation of single mRNAs. Some genes have evolved processes that allow the expression of alternative protein products by programming a non-standard translational event. Some genes specify decoding of a termination codon as an amino acid with continued decoding past the stop (readthrough), while others allow translation to shift into an alternative reading frame (frameshifting); in either case the result is expression of an alternative protein product. These processes are not 100% efficient so a given mRNA can program the expression of one protein by the canonical translational pathway while encoding an alternative structural form of the protein using a non-canonical translation event.

Mechanism of Translation

The mechanism of translation is conserved throughout all living things, though it differs in various details between the three domains—bacteria, archaea and eukarya. In general, translation in bacteria and archaea is somewhat simpler than in eukarya. In all three domains the ribosome is divided into two dissociable subunits. The large subunit in bacteria and archaea include two ribosomal RNAs (rRNAs), the 23S and 5S, while eukarya encode three: 26-28S, 5.8S and 5S. In all three the small subunit includes a

single rRNA, 16S in bacteria and archaea and 17-18S in eukarya. All ribosomes include many ribosomal proteins with bacteria having about 57, archaea about 68 and eukarya about 78 ribosomal proteins. Translation in each domain requires a different number of translation factors, accessory factors that facilitate the function of the ribosome. Bacteria require only three initiation factors, three elongation factors and four factors at termination. Eukarya and archaea have similar numbers of elongation and termination factors but require far more initiation factors, with eukarya requiring the most. Thus, translation in eukarya appears to be the most complex. This may partly reflect the greater physiological complexity of eukarya, especially metazoans, in general, but in addition the process of translation in eukarya is intrinsically more complex.

Translation Initiation

Initiation is the step of translation that differs the most markedly between the three domains. The mechanism used to specify the site of translation initiation has profound consequences for initiation control mechanisms. Bacteria and archaea use a different mechanism of initiation from both eukarya. In bacteria and archaea the ribosome can identify and directly bind to a site of translation initiation while in eukarya the ribosome generally identifies the initiation codon by binding to the 5' end of an mRNA and moving along it in a 5' to 3' manner, called scanning, until it encounters an initiation codon. Given the very different mechanisms employed, it should not be surprising to find that regulation of translational initiation also differs markedly. For example, mRNAs in bacteria and archaea are polycistronic because the ribosome can bind directly to internal initiation sites in the mRNA. Because eukarya scan for initiation sites, nearly all eukaryotic mRNAs are monocistronic. Eukarya have membrane-bound nuclei that physically separate the processes of transcription and translation while in the other two domains the processes occur in one compartment. This fact means that cross-talk between transcription and translation occurs in bacteria and archaea but not in eukarya. The possible mechanisms of translational control in the three domains are thus restricted by differences in structure and function.

Ribosomes use transfer RNAs (tRNAs) to perform the decoding of mRNA sequences into a polypeptide product. Each tRNA can have a single amino acid covalently added to its 3' end in a process called charging or aminoacylation. Each tRNA also includes a three nucleotide sequence (anticodon) that base pairs with one or more complementary sequences in the mRNA (codons). The ribosome insures that the correct tRNA is recruited to each codon and therefore that the correct amino acid is used in the process of protein elongation. The ribosome has three binding sites for tRNAs and each tRNA successively recruited to the ribosome proceeds through each of these three sites to perform distinct functions before it dissociates to be recycled and used again. The first site is the acceptor site (A-site) to which aminoacyl-tRNAs (aa-tRNAs) are recruited. The second is the peptide site (P site) to which the tRNA carrying the growing peptide chain is bound. The third is the exit site (E site) from which tRNA that have donated their amino acid to the growing peptide chain can dissociate to be re-aminoacylated so that they can be reused in translation.

Ribosomes cannot autonomously identify initiation codons, but rather require accessory initiation factors. Bacteria have three initiation factors, IF-1, IF-2 and IF-3, that interact with the 30S ribosomal subunit during initiation. IF-1 and IF-3 prepare the 30S subunit to initiate translation. IF-1 binds to A site of the ribosome and blocks premature association of aa-tRNAs to the A. IF-3 binds to the 30S subunit and blocks it from associating with the 50S subunit prematurely. IF-2 forms a ternary complex with the initiator tRNA (f-Met-tRNA) and GTP to promote its association with the P site of the 30S subunit. This ternary complex also directs tRNA binding to an initiation codon, most often AUG or GUG. GTP hydrolysis by IF-2 provides an error-correction function; hydrolysis only occurs when tRNA binds to a correct initiation codon. After GTP is hydrolyzed to GDP, the initiation factors dissociate and the 50S ribosomal subunit joins with it to form a complete ribosome. This allows the start of the elongation phase of translation by recruitment of another aa-tRNA to the A site.

No codons are dedicated exclusively to initiation. Instead, codons used during initiation are also used in the middle of structural genes. In addition, these codons may occur in untranslated regions or out of the normal reading frame used in translation. The ribosome must identify the small proportion of these codons at the beginning of structural genes, and ignore all others. Prokaryotic ribosomes directly participate in start site selection using a sequence near the 3' end of the 16S rRNA that is complementary to a sequence immediately upstream of true initiation codons. The upstream sequence is termed the Shine-Dalgarno (SD) box, commemorating the pair of researchers who first identified it. A correct initiation complex requires both tRNA to bind to an initiation codon and Shine-Dalgarno pairing to form immediately upstream. The distance between the two sequences is critical. Increasing or decreasing the distance between the initiation codon and the SD-box can drastically reduce translational initiation. This interaction is a potent target for translational regulation since blocking the SD-interaction can reduce initiation efficiency.

Because eukaryotic ribosomes generally bind scan to and initiate the first AUG codon in an mRNA, they need no further sequence information to identify initiation codons, and therefore do not require a Shine-Dalgarno interaction. It is critical, however, that eukaryotic ribosomes correctly identify the 5' ends of true mRNAs. To allow their identification, eukaryotic mRNAs have diagnostic structures at their 5' ends, a 5'-5' triphosphate linked guanosine, termed the 5' Cap. This structure is unique to eukaryotic mRNAs and is added post-transcriptionally to them but not structural RNAs. An elongation factor, a multi-protein cap recognition complex, eIF4F, binds to the structure and directs the binding to the mRNA of a eukaryotic initiation complex consisting of the small ribosomal subunit bound by a large number of protein factors. One of these factors is eIF2. Like IF-2, it forms a GTP-containing ternary complex with the initiator tRNA, called Met-tRNA. Hydrolysis of GTP is again coupled to dissociation of the bound initiation factors, recruitment of the large subunit, and the start of elongation. A second important initiation factor, eIF3, like IF-3, probably facilitates binding of the eIF2 ternary complex to the ribosome and insures the dissociation of the subunits, and is therefore critical to efficient translational initiation. In addition to these factors, eukarya employ many other initiation factors to facilitate scanning, initiation codon recognition, GTPase activation, factor release, and regeneration of the GTP form of eIF2.

Despite the fact that archaea initiate more like bacteria, archaeal initiation factors are more closely related to the eukaryotic counterparts. Because archaea do not have 5' Caps on their mRNAs or employ scanning, they lack the eIF4F factor. They do have homologues of the eIF2 factor and several other eukaryotic factors involved in initiation codon recognition, GTPase activation and factor release. These facts imply that archaeal initiation employs features of initiation in each of the other two domains, and that these mechanisms must have been present in the last common ancestor of the three domains of life. Bacteria and eukarya have since diverged to have very different initiation mechanisms while archaea have retained elements of each.

Elongation and Termination

The elongation phase of translation is universally conserved. Elongation involves the repeated addition of amino acids to a growing polypeptide chain. This addition occurs in the context of the three tRNA binding sites of the ribosome, the A, P and E sites. Amino acids to be added to the growing peptide chain are recruited to the ribosomal A site bound covalently to a tRNA. The covalent linkage, between the carboxyl-group of the amino acid and the hydroxyl group at the 3' end of the tRNA, is called an acyl linkage. After aa-tRNA is recruited to the ribosomal A site, an intrinsic activity of the ribosome catalyzes the transfer of the nascent peptide chain to the amino acid on the A site tRNA forming a peptide bond between the terminal carboxyl group of the nascent peptide and the free amino group of the amino acid on the A site tRNA. After peptide transfer the newly deacyl-tRNA (tRNA lacking any acylated amino acid) in the P site moves to a third site, termed E for exit, concomitantly with movement (translocation) of the new peptidyl-tRNA (pep-tRNA) into the P site. The cycle then repeats with recruitment of an aa-tRNA to the 3 nt codon immediately downstream of the codon bound to the pep-tRNA. It is important that mRNAs have no internal punctuation that enables the ribosome to identify the correct reading frame. The ribosome appears constrained to read only successive adjacent codons. How this is accomplished is, remarkably, still unknown.

Termination is really a specialized version of a normal elongation cycle which occurs when a special termination codon (UAG, UAA or UGA) occupies the A site. At that point the nascent peptide is released from the ribosome, and the two ribosomal subunits dissociate from the mRNA.

Most of the steps in the elongation cycle require the aid of elongation factors. Most organisms have only two elongation factors, EF1A and EF2 (eEF1A and eEF2 in eukarya), although fungi encode a third elongation factor, eEF3. A ternary complex of aa-tRNA bound to EF1A and GTP binds to the ribosomal A site. GTP hydrolysis provides a proofreading function thought to reduce translational errors. It separates the process into two steps, before and after GTP hydrolysis. Before GTP is hydrolyzed correct (cognate) ternary complexes bind essentially irreversibly while incorrect (near-cognate) ternary complexes tend to dissociate. After GTP hydrolysis, cognate aa-tRNAs essentially quantitatively undergo peptide transfer while near-cognate aa-tRNAs again tend to dissociate before peptide transfer. Until recently, error correction was thought to involve a kinetic proofreading mechanism where a difference in the rate of dissociation of correct (cognate) and incorrect (non-cognate) aa-tRNAs is used to eliminate errors. The two step process was thought to amplify error correction by providing two chances for incorrect, near-cognate aa-tRNAs to be rejected; this double sieve mechanism was used to explain how the ribosome achieves its low frequency of translational errors. More recently, the process of error correction was shown to involve an induced fit model in which cognate tRNAs induce a conformational change in the ribosome that increase the rates of two steps necessary to peptide bond formation: activation of the EF1A GTPase and accommodation of the aa-tRNA into the peptidyltransferase center, which is responsible for catalyzing peptide transfer to the aa-tRNA. Under this new model, increased accuracy results from near-cognate aa-tRNAs being unable to accelerate these processes resulting in fewer incorrect amino acids being incorporated.

Translocation of the pep-tRNA•mRNA complex appears to be an intrinsic function of the ribosome since it occurs in the absence of EF2. The rate of translocation is extremely slow, however. Recent kinetic and structural studies suggest the new pep-tRNA created after peptide transfer undergoes rapid structural fluctuations that EF2 can bias in favor of movement into the P site of the ribosome. In its GDP-bound form, EF2 is a structural mimic of the GTP-bound form of EF1A ternary complex and, like that complex, has high affinity for the empty A site. GTP hydrolysis causes a structural change to EF2 bound to the ribosome into a form that can fill the ribosomal A site when the pep-tRNA moves into the P site. Thus, GTP hydrolysis is essential to maximal rates of translocation.

Translational termination occurs when the ribosome encounters a termination codon (UAA, UAG or UGA) and is promoted by peptide release factors. The enzymology of termination differs between bacteria and eukarya. Bacteria have two peptide release factors, RF-1 and RF-2. The factors are codon specific, so that RF-1 recognizes the codons UAG and UAA and RF-2 recognizes UAA and UGA. A third factor, RF-3, has no codon specificity. It is a GTP-binding protein that may have a role in regulating the accuracy of codon recognition by the other two factors. In eukarya there are only two factors, eRF-1, the cognate of RF-1 and RF-2, and eRF-3, the cognate of RF-3. The termination factors bind to a ribosomal A site occupied by a termination codon and stimulate the ribosome's peptidyltransferase center to hydrolyze the acyl-bond between the nascent peptide and the tRNA, releasing the peptide from the ribosome. Another factor, ribosome recycling factor, or RRF, facilitates the dissociation of the ribosomal subunits from the mRNA.

Structural Basis of Translation

The most significant advance in decades in understanding of the process of translation came with the solution of a molecular structure of the ribosome and of complexes between the ribosome and various translation factors. We now have available models of the ribosome that provide atomic details of its structure and by extension, its function. Where once the translation system was

basically a black box, we now have atomic explanations for mechanisms underlying many of the steps in protein synthesis and insights into some forms of genetic control.

Structural models of the ribosome have greatly increased our understanding of the reactions that take place at the two active sites of the ribosome: the decoding center, which screens the mRNA-tRNA complex for accuracy, and the peptidyltransferase center, which catalyzes polymerization of the growing polypeptide. Both of these sites are composed largely or exclusively of RNA; this is consistent with a view in which the ribosomal proteins largely modulate the activity of RNA rather than participating in catalysis. The decoding center interactions play a direct role in maintaining translational accuracy. Decoding involves formation of base paired structures between a 3 nucleotide codon in the mRNA and a complementary anticodon in a decoding tRNA. The first and second positions of the codon must form Watson-Crick (WC) base pairs (G-C or A-U) with the anticodon; the third, or wobble position can make either WC or certain non-WC pairs. The non-WC pairs include U-G, U-I (Inosine), C-I or A-I. The structure of the decoding center mRNA•tRNA complex reveals the basis of this specificity. Elements of the ribosomal A site make multiple contacts with the codon and anticodon; these elements mainly consist of nucleotides of the small subunit rRNA but also include amino acid side chains from ribosomal protein S12. The interactions with the first and second base pairs require WC geometry and therefore non-WC base pairs could not form these interactions. Interactions with the third base pair do not require WC geometry, which allows acceptance of interactions using specific non-WC wobble base pairs.

Our understanding of how the ribosome insures accurate decoding has changed recently. The discovery of the structures in the ribosomal A and P sites that can interact with WC base pairs suggested a model in which the ribosome monitors the structure formed by the incoming aa-tRNA, recognizing when a cognate interaction has been formed (involving WC base pairs) and stimulating a conformational change in the ribosome that traps the aa-tRNA on the ribosome. Under this model, because near-cognate complexes (involving one non-WC interaction) would not be recognized, they would not be as efficiently recruited to the A site. This model would require the A and P sites to undergo rapid conformational changes to recognize a cognate complex but not a near-cognate complex. More recent data has shown that the A and P sites are much more rigid than previously thought and that they force both cognate and near-cognate complexes to bind in WC geometry. Cognates easily adopt this geometry but near-cognates forced into WC geometry create structural clashes that cause dissociation of the aa-tRNA from the A site.

Gene-Specific Translational Control of Gene Output

Translation is a complex process. The amount of protein expressed from a given gene, the gene output, can be regulated at multiple steps of translation. The rate of production of protein, in the absence of some other effect, reflects the frequency that ribosomes begin translating. As a result, many genes have evolved mechanisms to modulate this frequency. Other mechanisms indirectly regulate gene output without affecting initiation rate. For example, blocking translational elongation would also reduce gene output. Few systems have evolved that use such a block, and where they have the elongation block effects gene output indirectly by blocking downstream translational initiation by another ribosome (translational attenuation), causing early termination of transcription (transcriptional attenuation) or inducing mRNA degradation.

Alternative Pathways of Translational Initiation in Bacteria

Although translational initiation in bacteria normally occurs by direct binding of the initiation complex to the site of initiation, some genes have evolved a different mode of initiation, translational coupling. In translationally coupled systems ribosomes that initiate translation in an upstream gene continue translating one or more downstream genes by reinitiating at initiation codons overlapping or immediately adjacent to translational termination codons. At the same time, the RNA structure surrounding the downstream initiation codons precludes direct binding of ribosomes from solution. For example, the end of a gene may have the sequence AUGA, where the termination codon of the upstream gene (UGA) overlaps the initiation codon of the downstream gene (AUG). A translating ribosome reaches the end of the upstream gene, recognizes the UGA codon, and terminates translation by releasing the nascent peptide, allowing the last elongator tRNA to dissociate, and releasing the large ribosomal subunit. The initiation region of the downstream gene, which includes the AUG and upstream Shine-Dalgarno site, lies immediately adjacent to the termination site. Unlike eukaryotic ribosomes, the small subunit of prokaryotic ribosomes can bind to an initiation site ('ribosome binding site' or RBS) in the absence of either initiator tRNA or any initiation factor. Thus, the small subunit can be trapped on the mRNA after termination. Translation reinitiates when initiation factors and f-met-tRNA base paired to the AUG codon join the bound ribosome. This process theoretically can 100% efficient. The efficiency of reading the downstream gene depends on the frequency of initiation at the first gene so that a mechanism regulating the efficiency of translation of that gene can coordinately control expression of multiple downstream genes. To make the system entirely dependent on upstream translation, the RBS of the downstream gene is sequestered in a secondary structure; this structure blocks direct binding of initiation complexes but it can be opened up by the ribosome that translates through the upstream gene to allow initiation by coupling.

An alternative form of this type of control occurs when a ribosome translating through an upstream gene disrupts a secondary structure that sequesters the RBS of a downstream gene to block its recognition by initiation complexes. A ribosome translating the upstream gene may pause during elongation at a point where the secondary structure is unwound to release the RBS of the downstream gene so it can be recognized by a 40S subunit that would then initiate translation of the downstream gene. This system also allows translational co-regulation, but without reusing the ribosome.

The consistent feature of these systems is that upstream translation unmasks sites to make them available for translation initiation. Many mechanisms can accomplish this control, not all of which are strictly translational coupling. The use of upstream open reading frames (uORFs), as described below for translational attenuation, is a special case of this type of control.

Alternative Pathways of Translational Initiation in Eukarya

Translation of most eukaryotic mRNAs begins at the first AUG downstream of the 5' end. In some genes, however, the first AUG is not used and in some genes the 5' non-translated region includes many AUG codons not used for initiation. Translation initiation occurs in these genes by alternative mechanisms. There are three classes of alternative initiation mechanisms: leaky scanning, ribosomal shunting and internal initiation. In leaky scanning the ribosome ignores the AUGs that it encounters before the true initiation codon. The sequence context around these upstream AUGs tends to be different than that around bona fide initiation codons. This fact suggests that the ribosome scans for both the AUG and its surrounding sequence context, though the molecular mechanism of scanning for the context is not understood.

Ribosome shunting occurs in a very small minority of mRNAs. The mechanism is distinct from scanning despite the fact that the initiation complex binds to the 5' end of the mRNA, recognizing the eIF4 complex as in normal initiation. The complex begins scanning down the mRNA, but then bypasses a large segment of the 5' non-translated region ('shunts') before reinitiating scanning and initiating at the first AUG it then encounters. The first example of shunting came from the plant virus, cauliflower mosaic virus, but there are several other examples.

Internal initiation is a much more common mechanism than shunting, but still occurs on a small minority of mRNAs. Unlike either scanning or shunting, in this mechanism the initiation complex binds directly to a site within the body of the mRNA. Since the complex does not bind to the 5' end of the mRNA this form of initiation does not necessarily require the 5' cap. In fact, eukaryotic viruses have evolved systems that block normal translational initiation dependent on the 5' cap. This block strongly decreases translation of endogenous cellular mRNAs that use translational scanning. Normally internal initiation is rather inefficient but when scanning is blocked translation of the viral mRNAs by internal initiation becomes much more efficient because the endogenous transcripts no longer compete for the translational machinery. Internal binding of the initiation complex is directed by a highly-structured region in the 5' non-translated region called an internal ribosome entry site, or IRES. Some IRESs stimulate initiation by binding translation initiation factors that in turn recruit the preinitiation complex. Other IRESs directly bind to the ribosome to recruit it without the aid of any initiation factor. An extreme case is the IRES from the cricket paralysis virus (CrPV), which requires no initiation factors or even the initiator tRNA. For the CrPV IRES a secondary structure that mimics the tRNA base paired to an initiation codon occupies the ribosome P site. This structure then recruits an EF1A ternary complex to the next codon to initiate protein synthesis.

Co-Translational Control of Gene Transcription in Bacteria: Transcriptional and Translational Attenuation

Transcription and translation in bacteria are not restricted to physically separated sub-cellular compartments, as they are in eukarya. This provides the possibility of a form of genetic control in which transcription is coupled to continued translation of the nascent mRNA. Certain bacterial operons are controlled at the level of transcriptional termination in the leader region of the operon. Termination occurs when transcription and translation of the leader region becomes uncoupled. This process, termed transcriptional attenuation, governs expression of several amino acid biosynthetic genes and was first recognized in the *trp* and *his* operons. Ribosomes bind to and begin translating an upstream open reading frame (uORF) in the leader region of the nascent transcripts of these genes. In the *trp* and *his* systems, the uORFs contain several tryptophan or histidine codons. In addition to this uORF, the leaders contain RNA sequences that can form two alternative structures: a hairpin structure located downstream of the uORF that when formed in the nascent mRNA signals termination of translation (terminator hairpin) and an alternative hairpin located between the terminator hairpin and the uORF that cannot signal termination (attenuator hairpin). When the amino acids are present in sufficient amounts, the ribosome reads through the uORF on the nascent mRNA, blocking formation of the attenuator hairpin. The terminator hairpin forms and transcription terminates without continuing into the downstream amino acid biosynthetic genes. During starvation for these amino acids, however, ribosomes reading the uORF stall at these codons because of lack of sufficient cognate EF1A ternary complexes. The stalled ribosomes allow formation of the attenuator hairpin, so the terminator hairpin is not formed and the polymerase continues on, transcribing the biosynthetic genes ultimately leading to increased synthesis of the corresponding amino acid. Thus, the lack of continuing translation is transduced to a signal to continued transcription of the biosynthetic genes as a feedback control mechanism.

Other similar systems modulate expression using a uORF, but the regulation is at the level of translational initiation. A dramatic example comes from the *cat86* gene of *Bacillus subtilis*. This gene encodes an enzyme that acetylates the antibiotic chloramphenicol, a protein synthesis inhibitor that blocks peptidyltransferase. The gene has a uORF that is translated co-transcriptionally. The nascent polypeptide is itself a peptidyltransferase inhibitor, so that ribosomes translating the uORF become paused because the nascent peptide blocks further extension of the protein. This pause is normally transient but if chloramphenicol is present it binds to the stalled nascent peptide and the stall becomes extremely prolonged. The paused ribosome disrupts a mRNA secondary structure that when formed sequesters the RBS of the *cat86* gene. Pausing thus makes the RBS available for ribosomes to bind and initiate translation of *cat86*, ultimately leading to inactivation of chloramphenicol. In this case a gene exquisitely sensitive to inhibition by chloramphenicol transduces blockage of translation into stimulation of translation. This type of control has been observed in multiple other drug resistance genes in bacteria.

Control of Translational Reinitiation

Ribosomes on some uORF-containing eukaryotic mRNAs scan as normal but initiate translation on the upstream AUG codon rather than at the initiation codon of a downstream structural gene. Ribosomes can translate the uORF into a short oligopeptide and then reinitiate scanning, eventually recognizing the downstream initiation codon and translating the structural gene. This process is called translational reinitiation and constitutes another form of alternative translational initiation. Translational reinitiation occurs on a small minority of mRNAs and has been best studied in the *GCN4* gene of the yeast *Saccharomyces cerevisiae*.

The *GCN4* mRNA has four uORFs. Ribosomes scanning from the 5' end initiate translation at either the first or second uORF after which the ribosomes reinitiate scanning. During the scanning they must re-stock themselves with initiation factors, including methionyl-tRNA^{Met}•eIF2•GTP ternary complex, in order to be able to reinitiate at a downstream AUG. If they do so and become competent to reinitiate before scanning past the second pair of uORFs the ribosomes will initiate on them, but if they become competent only after scanning past the uORFs they may initiate on the *GCN4* gene. Yeast cells starved for amino acids have a lower concentration of eIF2 ternary complex, so that during starvation it would take longer for the reinitiating ribosomes to become competent for translation. In this case, more ribosomes bypass the second set of uORFs and translate the *GCN4* gene. The Gcn4 protein is a transcriptional activator of amino acid biosynthetic genes, so this system is used to turn on expression of *GCN4* during amino acid starvation by increasing expression of Gcn4 resulting in higher expression of amino acid biosynthetic genes and increased synthesis of the amino acid responsible for the starvation. Genes homologous with *GCN4* exist in metazoan species and use similar mechanisms to regulate translation.

Translational Repression

Translational repression is a ubiquitous and common form of translational control. The best-known example comes from ribosomal proteins in bacteria. During balanced growth, the amount of each ribosomal protein and the rRNA components of the ribosome are equimolar and all ribosomal proteins produced rapidly bind to pre-ribosomes during ribosome assembly. When this balance is disturbed and the ribosomal proteins are present in excess, certain of the ribosomal proteins bind to their own mRNAs inhibiting translation initiation of entire operons comprised largely of genes for ribosomal proteins including the one that binds the mRNA. This mechanism achieves feedback control of ribosomal proteins, reducing their expression when it is in excess, and contributes to homeostasis in ribosome biogenesis. The binding site for the proteins lie within the 5' non-coding region and block access by ribosomes to the ribosome binding site of the first controlled protein. Through translational coupling, down regulation of the first protein can proceed down the mRNA to other genes located on the same mRNA.

A second well-known example is the gene 32 protein of bacteriophage T4, which is a DNA binding protein that binds randomly to single stranded DNA. It can also bind specifically to a pseudoknot structure in the 5' untranslated region of its own mRNA blocks ribosome binding at an adjacent RBS.

One eukaryotic repressor, IRE-BP, works by a very similar mechanism. The protein is the cytosolic isozyme of the mitochondrial enzyme aconitase, but is also a translational repressor that is responsive to the concentration of ferric iron (Fe³⁺). IRE-BP has an iron-sulfur cluster that loses a single Fe³⁺ when iron concentration is low. The region of the protein normally bound by this Fe³⁺ can then bind to an iron response element (IRE) in the 5' non-coding region of the ferritin mRNA. When bound, IRE-BP blocks access by the initiation complex to the mRNA. When Fe³⁺ concentration is high another Fe³⁺ can bind to IRE-BP, reducing its affinity for the IRE, and eliminating its repression of ferritin. Because ferritin protects the cell from oxidation by chelating intracellular Fe³⁺ the increased expression of ferritin when Fe³⁺ concentration insures cell viability.

Other eukaryotic translational repressors function differently by binding to sites in the 3'-noncoding regions of mRNAs, which would not directly block access by the scanning ribosome to the mRNA. Instead their effect must be more long-ranged. This long range effect involves the fact that mRNAs in eukarya adopt a circular structure in which the 5' and 3' ends are held in close contact by specific RNA binding proteins that recognize the 5' cap (eIF4F) and 3' poly(A) tails (poly(A)-binding protein or PABP). It appears that the initiation complex recognizes this PABP•eIF4F complex to bind the mRNA and initiate scanning. The translational repressors bound to the 3'-noncoding region block ribosome binding by interfering with recognition or formation of the eIF4F•PABP complex.

Control by blocking Cap recognition is especially common in maternal mRNAs during the early stages of development. There are two main ways that this is accomplished. First, mRNAs intended to be stored, untranslated in oocytes frequently have very short poly(A) tails, too short to recruit PABP. In the absence of PABP the mRNAs are not actively recruited to translation. During early development, these mRNAs can be translationally activated by extending their poly(A) tails, which then bind PABP and are then translated. On the other hand, some mRNAs that had been translationally active are repressed by deadenylation, which can block their translation and often lead the degradation of the mRNA. A second mechanism involves proteins like Cup and Maskin, two proteins that bind brought to the 3' non-coding regions of target mRNAs by their affinity for site specific RNA binding proteins bound there. Cup and Maskin are mimics of a translation factor eIF4E-BP that binds to the eIF4E cap binding protein of the eIF4F complex. When eIF4E is bound by eIF4E-BP or one of the mimics it cannot associate the eIF4F protein that forms the bridge to PABP (eIF4G); inability to form that circularized complex blocks translation of the proteins. The eIF4E-BP is a global regulatory factor, which we will return to below, but Cup and Maskin function only on mRNAs to which they are targeted by associating with their 3' non-coding regions.

Control of mRNA Degradation

While at first the process of mRNA degradation would seem unrelated to the issue of translational control, much degradation actually occurs either in the context of ongoing translation, or is actually coupled to the process of translation. Especially in eukarya, where mRNAs have half-lives very much longer than in bacteria, gene output can often be profoundly affected by a change in mRNA stability.

A classic example of co-translational degradation comes from mammalian tubulin genes. In addition to long term transcriptional control, both α and β tubulin are subject to very rapid co-translational control by mRNA degradation. The mechanism of this control is better understood for β -tubulin, though regulation of α -tubulin appears quite similar. When the concentration of free β -tubulin subunits is high the mRNA for β -tubulin is rapidly and specifically degraded. The signal for this degradation is surprisingly the first four amino acids of the nascent polypeptide. As this peptide, Met-Arg-Glu-Ile, emerges from the ribosome some cellular factor (perhaps β -tubulin itself) recognizes it and activates an unknown endonuclease which cleaves the mRNA, leading to its ultimate degradation. This system provides a very rapid response to the presence of excess subunits as, for example, when microtubules depolymerize into tubulin monomers, or to adjust an excess of β over α -subunits.

A second example of co-translational control concerns degradation of mRNAs containing premature termination codons (nonsense mediated decay or NMD). The mRNA of a nonsense mutant gene can be much less stable than the identical mRNA lacking the nonsense mutation. When a translating ribosome encounters a premature termination codon there are a group of ribosome-associated proteins that sense the presence of the nonsense codon and induce NMD. Exactly how that signal is sent remains somewhat controversial. In the simple eukaryote, *S. cerevisiae*, the sensitivity to degradation appears to derive from the fact that premature termination codons can create extremely elongated 3' non-coding regions consisting of all of the normally coding region distal to the mutation and the normal, usually short, normal 3' non-coding region. The NMD system seems to stimulate degradation if the 3' non-coding region is much longer than normal. In higher eukaryotes the signal appears to be the presence of a splice junction—a position in the mRNA from which an intron has been excised—downstream of the termination codon. Splice junctions normally do not occur distal to a true termination codon, so finding one downstream identifies the terminator as premature. Premature termination codons could occur because of a genetic mutation but probably much more frequently they result from incorrect splicing in which an intron remains in the mRNA; a ribosome reading such an mRNA should rapidly encounter an in-frame termination codon in the intron. NMD, by inducing degradation of the mRNA prevents accumulation of an abnormal protein that could be detrimental to the cell.

For some mRNAs sequence-specific RNA binding proteins recognize special sites to activate mRNA degradation. Interestingly, the same IRE-BP protein that regulates translation of ferritin mRNA in response to Fe^{3+} also regulates transferrin, the protein responsible for importing iron into eukaryotic cells. Transferrin must be regulated oppositely to ferritin since iron is limiting in the growth medium transferrin must be abundant to allow recruitment of the diminished supply; when iron is abundant transferrin must be down regulated so that the cell is not oversupplied with the potentially damaging ion. When Fe^{3+} concentration is low, IRE-BP binds to multiple IREs in the 3' non-coding region of the transferrin mRNA. The IREs are interspersed with instability elements, and bound IRE-BP interferes with their function to stabilize the mRNA. In high Fe^{3+} , IRE-BP dissociates from the IREs and the instability elements then promote rapid degradation of the mRNA, reducing the concentration of transferrin in the cell and slow import of Fe^{3+} .

There are many other examples of genes with instability elements in their 3' non-coding region and many of them function constitutively to maintain a short half-life for the mRNA. These elements allow for rapid readjustment of mRNA pools by either increasing or decreasing the rate of transcription of the mRNA. These elements are common in mRNAs encoding regulatory proteins, such as transcription factors.

Global Control of Translation

In addition to the many forms of gene-specific regulation, translation is often regulated globally by mechanisms that modulate the activity of translation factors. Cells employ global regulatory processes themselves to regulate translation efficiency by modulating the activity of translation factors. One purpose of this regulation is to diminish expression of proteins encoded by invading viruses by partially inactivating the translational machinery. In addition, cytotoxic viruses upon infection commonly take over the genetic machinery of the infected cell, directing much of the synthetic capacity of the cell to production of virus-encoded proteins. This shift usually involves inhibition of cellular translation through covalent modification (phosphorylation or proteolysis) of cellular translation factors. Viral genes have evolved a lower dependence on these factors for their expression so that they compete more effectively for the translational machinery under these circumstances than do cellular genes.

Phosphorylation of translation factors is the most common form of global translational control and the commonest targets are the elongation factors eIF2 and eIF4E. Phosphorylation of eIF2 reduces its activity while phosphorylation of eIF4E stimulates its activity.

Reticulocytes dedicate virtually their entire protein synthetic machinery to the production of the protein hemoglobin. The rate of synthesis of the apoprotein and synthesis of its iron-containing heme cofactor must be carefully co-regulated. Reticulocytes express an eIF2-specific protein kinase, heme regulated inhibitor (HRI), that phosphorylates the α -subunit of eIF2 in conditions of low heme. When phosphorylated, eIF2 binds much more tightly to its recycling factor, eIF2B, causing eIF2B to become sequestered and

unable to recycle other eIF2•GDP to the active form of eIF2•GTP. This in turn reduces the availability of eIF2•GTP and thus of met-tRNA•eIF2•GTP ternary complex. Translation initiation declines as the concentration of ternary complex falls, so that the ultimate effect of eIF2 phosphorylation is reduced translation. This reduction is used to equalize the concentration of apohemoglobin and the heme cofactor, whose concentration falls in low iron conditions.

A similar mechanism of phosphorylation inhibits protein synthesis in virus-infected cells. A homolog of HRI, the dsRNA-dependent protein kinase (PKR), phosphorylates eIF2 α in virus infected cells. This reduces protein synthesis which reduces virus yield from the infected cells. A third homolog, the product of the *GCN2* gene in the yeast *S. cerevisiae* is the sensor of amino acid starvation in the *GCN4* translational reinitiation scheme described above. Cells starved for amino acids accumulate deacylated tRNAs which bind to Gcn2p activating its eIF2 α kinase activity. This leads to a reduction in eIF2 ternary complex. The reduction is not enough to affect bulk protein synthesis, as PKR and HRI do, but enough to reduce the efficiency that ribosomes scanning past the first of the *GCN4* uORFs regain competence to reinitiate translation. In starved cells the ribosomes tend to become competent after moving farther down the mRNA, and so tend to initiate translation on the *GCN4* gene rather than on the two inhibitory uORFs, causing an increase in translation of *GCN4*. This system is an unusual case of a global change in the translation system (reduction in eIF2B activity) that has evolved to regulate a single gene (*GCN4*) because of its exquisite sensitivity to reductions in eIF2 ternary complex.

Phosphorylation of eIF4E, the cap-binding factor, and of its antagonist, eIF4E-BP, are examples of the opposite form of global control. Phosphorylation of eIF4E or eIF4E-BP is correlated with increased translation, rather than diminished; the mechanism of this eIF4E effect is not understood but eIF4E-BP is much better understood. In higher eukaryotic systems, various mitogens stimulate phosphorylation. Presumably cells stimulated to proliferate or initiate developmental programs require an increase in translation. Modulating eIF4E activity is especially effective because of its very low-abundance relative to other initiation factors, and because it is critical to the first step in recruitment of ribosomes to the mRNA. Phosphorylation of eIF4E-BP decreases the strength of its association with eIF4E. Since eIF4E-BP competes with the interaction between eIF4E and the PABP-binding factor, eIF4G, decreased binding of eIF4E by eIF4E-BP leads to more efficient formation of circular mRNAs and therefore more efficient translation initiation. This effect is used to modulate translation in response to external nutrients. When cells are deprived of nutrients or growth factors, eIF4E-BP is unphosphorylated, binds to eIF4E and reduces translation globally. When cells are stimulated by addition of nutrients or growth factors, eIF4E-BP is phosphorylated by the TOR kinase pathway, reducing its affinity for eIF4E and stimulating higher translation. Misregulation of this pathway can result in uncontrolled growth and cancer.

The cap-recognition complex is also subject to the opposite type of control by specific degradation. During picornavirus infection eIF4G is specifically cleaved by a protease encoded by gene 2A of the virus. This cleavage reduces translation, though not completely. Since picornaviruses use a cap-independent method of initiation reducing efficiency of cap-recognition would tend to increase the ability of the picornavirus mRNA to compete for the limiting supply of ribosomes in the cell, thus increasing its relative efficiency. The point of this control may not be to completely suppress cellular mRNA translation, but only to maximize viral expression.

Translational Accuracy

Control of the primary structure of proteins is a second ubiquitous, but perhaps not as prevalent, form of translational control. This type of control has been called 'recoding' to suggest that the rules of translational coding are changed to result in an unconventional or non-canonical event. In most cases this type of control is used to allow a single gene to specify two structurally related, yet distinct primary gene products. Termination codon readthrough, the simplest of these events, results in the insertion of an amino acid at a termination codon. Readthrough is a stochastic event, usually much less than 100% efficient. As a result, readthrough allows expression of two forms of a protein: a protein resulting from normal termination and a second consisting of the first protein fused to the product of the reading frame downstream of the terminator. Other events call for the ribosome to shift its reading frame either by reading a codon overlapping one in the previous frame, or by causing the ribosome to bypass a short stretch of codons. These types of events resemble superficially the kinds of errors that occur during translation, though the efficiency of the events during recoding is several orders of magnitude higher. Understanding recoding requires first a consideration of the mechanism of translational errors and of the mechanisms used by the ribosome to forestall them.

Types of Translational Errors

Missense errors, the simplest type of translational error, occur when one amino acid is inserted in the place of another. Missense errors result from either incorrect tRNA aminoacylation or recruitment of an incorrect tRNA to the ribosome. They are the most frequent type of translational error. The translational machinery has to compromise the cost of translational inaccuracy and the advantage of increased translation speed. To the extent that translation rate is increased the ribosome will tend to accept a greater proportion of erroneous, non-cognate tRNAs. To reduce translation errors below the observed frequency would require a significant reduction in translation elongation rates. The observed rate of errors probably optimizes these antagonistic negative and positive effects.

Studies of several different translational misreading errors suggested that they occur at a rate of about 5×10^{-4} per codon. Although a rate of 5×10^{-4} per codon seems low frequency it results in inaccurate expression of a significant proportion of proteins.

For example, the protein β -galactosidase is 1000 amino acids in length. Errors occurring at 5×10^{-4} per codon would result in 40% of proteins having at least one missense error! Yet missense errors tend to have a relatively low phenotypic effect since most errant proteins retain full activity, and few have seriously lowered activity. More recently, attempts to comprehensively measure all possible missense errors by single tRNAs have revealed a more complex phenomenology of error. First, missense errors essentially cannot be measured on non-cognate codons (those that form fewer than two base pairs with the misreading tRNA). This is consistent with an abundance of biochemical data showing that non-cognate tRNAs are recruited extremely slowly to the ribosomal A site, essentially never getting to even the first step of codon recognition. The surprising result of this work, however, was the finding that most near-cognate codons (those making two base pairs with the codon) are misread extremely infrequently. Errors at most near-cognate codons occur at frequencies of about 2×10^{-5} per amino acid incorporated. Some codons, however, experience much more frequent errors. Those codons are read by the misreading tRNA using a mismatched base pair that appears to have similar geometry to a normal, Watson-Crick pair (A-U or G-C) suggesting that higher frequency errors occur when a mismatched base pair cannot be distinguished from a correctly matched pair. These errors only occur at frequencies between about 10^{-4} and 3×10^{-3} ; this low frequency results from the fact that the pairs require a nucleobase to be in a non-physiological tautomeric form (enol rather than keto or imino rather than amino), which occur at frequencies near 10^{-4} , similar to the error rate observed, suggesting that ability to tautomerize may have a large effect on the error rate.

The second general class of errors are those that cause premature termination of translation. These are termed processivity errors since they interfere with the processive nature of translation. Processivity errors occur on average at approximately the frequency of missense errors. Again, that would imply a significant loss in terms of gene output because of these errors. At a rate of 5×10^{-4} terminations per codon, only about 60% of ribosomes that begin translating β -galactosidase would actually produce a full-length product. These errors generally have a much more serious effect on the activity of the gene product. The vast majority of C-terminally truncated products would retain no enzymatic activity, and would indeed be subjected to rapid degradation *in vivo*. Usually only those proteins retaining all but the most C-terminal portion of the protein retain significant activity. It is perhaps surprising that the translational machinery has not evolved a more efficient correction mechanism for these errors given their seriousness. This failure implies that the compromise in terms of the rate of translation elongation would be too drastic to reduce these errors further.

The simplest kind of processivity failures are those in which the process of elongation is aborted prematurely. Surprisingly, few of these errors are caused by mistaken recognition of a sense codon by peptide release factor, so these errors are not improper termination events *per se*. Instead, the vast majority occurs when pep-tRNA spontaneously dissociates from the translating ribosome ('ribosome drop-off'). Cells have a special enzyme that removes nascent peptides from these tRNAs, peptidyl-tRNA hydrolase. When this enzyme is inactivated cells rapidly fill with pep-tRNA, underscoring the frequency of the error. Treatments or genetic states that favor missense translation also stimulate this error, suggesting that incorrect pep-tRNAs may tend to dissociate from the ribosome.

Translational frameshifting is the second type of processivity error since a ribosome that changes reading frame cannot complete the intended translational product, and in fact should rapidly encounter a termination codon in the shifted frame. Perhaps significantly, frameshifting errors occur at least ten-fold less frequently than either missense errors or ribosome drop-off. Since these errors should be no more serious than other processivity failures in terms of enzyme activity, their lower occurrence cannot reflect a greater selection against them. Rather it may reflect a fundamental feature of the error mechanism.

Spontaneous frameshifting normally occurs by changes of single nucleotides either in the 5' or leftward direction (-1), or the 3' or rightward direction ($+1$). Frameshifting has been studied as phenotypic suppression of single base pair insertion or deletion mutations. Judged by the level of suppression, $+1$ frameshifting appears to occur much more frequently. Sequence contexts greatly affect the efficiency of frameshifting because suppression can vary strikingly among various frameshift mutations. This implies that there are specific signals that stimulate frameshifting. The nature of the signals was made clearer from analysis of programmed frameshift sites, sequences in genes that program highly-efficient frameshifting (see below).

Genetics of Translational Accuracy

The classical approach to genetic analysis of translational accuracy was to identify suppressor mutations that restore normal activity to missense or frameshift mutant forms of a reporter gene. For example, using a gene that had suffered a 1 bp insertion and therefore was non-functional, one could identify second-site suppressors that restored normal expression of the gene. Such frameshift suppressor mutations affect tRNAs, ribosomal proteins, rRNA, and translation factors. Similarly, suppressors could be identified that promoted readthrough of premature termination codons or allowed bypass of missense mutations. These experiments have identified factors responsible for maintaining translational accuracy.

tRNA mutations

Seemingly the easiest of the suppressors to understand were the tRNA suppressors. Nonsense, frameshift and missense suppressors all seem to work in the same manner. By changing the sequence of the anticodon the decoding properties of a tRNA are changed. Nonsense suppressors have an anticodon complementary to one of the nonsense codons. Most $+1$ frameshift suppressors have anticodons expanded from three to four or more. Similarly, missense suppressors have anticodons corresponding to the codon that must be misread. Creating these suppressors is complicated by the fact that most aminoacyl-tRNA synthetases contact bases in anticodons to discriminate among possible substrates. Changing the anticodon can also change recognition by the synthetase. This is most clearly an issue for the missense suppressors, but inefficient aminoacylation would reduce the function of any of the suppressors. As a result, only a few of each class of suppressor have been identified.

Recent work has shown that the accepted model for +1 frameshift suppressors is incorrect for a major class of mutations, and might be invalid in general. The Quadruplet-Decoding model proposed that the expanded anticodon of +1 frameshift suppressors allowed a 4 bp codon•anticodon interaction in the ribosomal A site, resulting in 4 nt translocation catalyzed by EF2. This model cannot explain frameshifting by the tRNA^{Pro} family of suppressors since post-transcriptional modification of the anticodon loops of these tRNAs preclude the putative 4 bp codon•anticodon interaction. For these tRNAs, and probably for all others, it appears that the suppressing tRNA causes a normal 3 nt translocation, but that the pep-tRNA slips +1 on the mRNA while in the ribosomal P site. This Peptidyl-tRNA Slippage model can explain suppression by all of the classes of frameshift suppressing tRNA mutations though direct evidence supporting the model for many of them is not yet available.

Ribosomal mutations

Since translational errors occur in the context of the ribosomal decoding sites one might expect that some suppressors would affect ribosomal components. In fact, some of the earliest suppressor mutations affected the ribosomal proteins S4, S5 and S12 of *E. coli*. Mutations in S12 cause resistance to the antibiotic streptomycin concomitant with reduced error frequency, while those in S4 or S5, called *ram*, for 'ribosomal ambiguity', increase the error frequency. These data suggest that the three ribosomal proteins may form the core of an accuracy center on the ribosome. Significantly, the three are proteins of the small subunit of the ribosome, the site of codon•anticodon pairing, suggesting that they may directly modulate the interaction.

Mutations affecting the rRNA in both subunits of the ribosome can stimulate translational errors. Three regions of the single rRNA of the small subunit, within which the codon•anticodon pair forms, can mutate to suppress either frameshift or nonsense mutations. Frameshift suppressing mutations fall in the part of the rRNA in the decoding center of the ribosome, which is composed of nucleotides from several regions of the small rRNA. These regions are in direct contact with the codon•anticodon complex in the A and P sites as described above. Other frameshift suppressing rRNA mutations affect the large subunit rRNA, 23S rRNA in bacteria. These fall within the α -sarcin loop, a region so-named because it is cleaved by the cytotoxic nuclease α -sarcin.

Translation factor mutations

The final class of suppressors affect the translation elongation factors EF1A, and its eukaryotic homologue, eEF1A, and the peptide release factors. Mutant forms of bacterial EF1A and yeast (*S. cerevisiae*) eEF1A have the same effect of suppressing nonsense or frameshift mutations, or both. The mutations are not clustered in the molecule, and in fact affect either of its two functionally distinct regions, the GTP-binding and tRNA-binding domains. The exact mechanism of suppression is unclear. Those affecting the GTP-binding domain may affect the kinetics of GTP hydrolysis, which would be expected to perturb discrimination between correct and incorrect tRNAs. Those in the tRNA-binding domain may change the interaction between the EF1A ternary complex and the ribosome, perhaps stabilizing the interaction of non-cognate tRNAs, which again under that model would tend to reduce discrimination.

Availability of peptide release factors influence the frequency of nonsense codon readthrough both in vivo and in vitro. Reduction in the effective concentration of release factors tends to allow readthrough, to varying degrees, of all three types of nonsense codons. The amino acid inserted tends to be one that is near in sequence to the nonsense codon. This implies that when the rate of recognition of a nonsense codon is limiting, the ribosome will accept incorrect tRNAs. This is consistent with the idea that ribosomal accuracy is kinetically controlled. In yeast, an epigenetic state can arise in which peptide release factor is limiting. The state is brought on by aggregation of the factor and results in increased nonsense codon readthrough. This situation resembles a prion infection since the condition is heritable but not genetically encoded. This is an active area of investigation given its clinical significance as a model system.

Programmed Alternative Translation

Genetic control by induced alteration of the rules of translation occurs ubiquitously, but infrequently. The majority of programmed alternative translation systems occur in viruses or virus-like genetic elements. A few cellular genes use this form of control and the number is slowly growing. This form of control is expected to remain rare. In most cases the alternative translation system provides the capacity to express a C-terminally extended form of a protein. This extended form is usually required for a morphogenetic process related to the lifecycle of the virus or virus-like element. A minority of genes use this system to express alternative proteins with different enzymatic features, or as a system of autogenous or feedback control.

Programmed Readthrough of Termination Codons

Readthrough of termination codons is arguably the simplest form of alternative decoding. The sequence context surrounding the termination codon probably acts to reduce the efficiency of translational termination and thus increase the probability that a non-cognate tRNA will recognize the nonsense codon. Some programmed readthrough sites are quite simple. In Sindbis virus, a positive-strand RNA animal virus, expression of a full-length nonstructural polyprotein requires readthrough of a single UGA codon. Readthrough requires only the sequence UGA-C. Peptide release factor recognizes true termination codons using a tetranucleotide signal consisting of the codon and its 3'-neighbor nucleotide. An inappropriate 3' nucleotide can drastically reduce the rate of termination. This appears to be the mechanism of readthrough suppression in Sindbis virus; slow recognition of this very poor termination sequence allows recognition of the UGA codon, probably by tryptophanyl-tRNA^{Trp}.

Other programmed readthrough sites are much more complicated. An example of a complex readthrough site comes from the retrovirus Moloney murine leukemia virus (MoMLV). Expression of the *pol* gene (for polymerase), which encodes the enzymes associated with reverse transcription and integration, are expressed as a translational fusion to the structural proteins encoded by the upstream *gag* gene (for group specific antigen). The fusion occurs by readthrough of a single UAG codon separating the two reading frames. The sequence context following this codon determines the frequency of readthrough, about 5–10%. Maximal readthrough requires a 54 nt downstream region which folds to form a pseudoknot. A pseudoknot is a complex secondary structure in which the loop portion of a stem-loop structure basepairs with an immediately flanking sequence. The readthrough requires this secondary structure but not most of its primary sequence. Only the sequence of two short single-stranded regions are actually required; their function in the mechanism is not understood. The pseudoknot causes misreading of the UAG codon as glutamine, which would require a U•G wobble interaction at the first position of the codon.

Perhaps the most bizarre form of programmed readthrough occurs during co-translational insertion of two unusual amino acids which have been termed the 21st and 22nd amino acids since they are encoded, although in an unusual sense. The 21st amino acid is selenocysteine and the 22nd is pyrrolysine. They are encoded at specialized UGA codons. More is known about the mechanism of selenocysteine incorporation but the same mechanisms appear to be used for pyrrolysine. For selenocysteine, the context surrounding the targeted UGA codons prohibits translation termination and promotes recognition of the codon by selenocysteyl-tRNA^{Sec}. This tRNA has an anticodon complementary to the UGA codon. Because of its unusual structure it cannot bind EF1A, but instead binds to a specialized cognate factor, the SELB protein. SELB in turn binds to a specialized secondary structure called the SECIS (selenocysteine insertion sequence). When bound to the SECIS, SELB delivers selenocysteyl-tRNA^{Sec} into the A site at the UGA codon. In bacteria, the SECIS is located immediately downstream of the UGA, but in eukarya it is in the 3' non-translated region of the mRNA. In eukarya the SECIS and tRNA recognition are encoded in two interacting proteins. The SECIS recognition protein, SBP2, recruits a ternary complex consisting of the specialized selenocysteine elongation factor, EFsec, bound to selenocysteyl-tRNA^{Sec} and GTP. In a sense, selenocysteine incorporation is an example of specialized nonsense suppression since it employs a dedicated cognate tRNA for the UGA codon.

Programmed Translational Frameshifting

The second form of programmed alternative decoding occurs when a sequence in a gene causes the translating ribosome to shift into a new reading frame while continuing elongation. The most common form of programmed translational frameshifting shifts the ribosome in the –1 direction. –1 frameshifting occurs in many metazoan viruses, including retroviruses, in various plant viruses, lower eukaryotic virus-like elements, and in bacterial insertion sequences; –1 frameshifting is used much less frequently in cellular genes. Frameshifting occurs on a slippery heptameric sequence of the form X-XXY-YYZ, shown in codons of the unshifted frame, by simultaneous slippage of two tRNAs from XXY-YYZ to XXX-YYY. A downstream secondary structure, a pseudoknot in most eukaryotic sites and a stem-loop in most prokaryotic sites, stimulates slippage. How the structure does this is not understood, though it involves more than just pausing the ribosome during translation. In bacteria a second site upstream of the slippery heptamer stimulates slippage. At this site the Shine-Dalgarno sequence of the 16S rRNA engages the mRNA and appears to literally pull the mRNA to stimulate slippage of the tRNAs.

+1 frameshifting is much less common. It was first discovered in a yeast retrotransposon (a transposable genetic element related to retroviruses), but is also found in cellular genes in *E. coli*, yeast, and mammalian cells. In each case frameshifting occurs when a poorly recognized codon occupies the A site while a special codon occupies the P site. In most cases, a tRNA occupies the P site codon that can slip +1 while still maintaining at least 2 bp with the mRNA. In some cases, though, frameshifting appears to occur without the need for slipping. In these cases a special feature of the pep-tRNA stimulates out-of-frame decoding in the A site, shifting reading in the +1 direction. In yeast it is clear that the feature causing this behavior is the fact that the pep-tRNA is a near-cognate tRNA, it is an isoacceptor that cannot form a normal wobble interaction with the codon. A purine•purine clash in the wobble position by the pep-tRNA in some way disrupts recognition in the A site, causing out-of-frame decoding.

Programmed Translational Bypassing

Translational bypassing is the rarest form of programmed alternative decoding. To date it has been demonstrated only in the bacteriophage gene 60, encoding topoisomerase. This gene is interrupted by a 50 nt insertion that is present in the mRNA. Despite the interruption the ribosome is able to decode the gene, bypassing the 50 nt entirely. Bypassing depends on several stimulatory features: matching 'take-off' and 'landing' codons, an in-frame termination codon immediately after the take-off codon, a stem-loop structure encompassing these two codons and a nascent peptide sequence encoded immediately upstream of the take-off codon. The matching take-off and landing codons reflect the need for the pep-tRNA to dissociate from the mRNA and re-pair after the 50 nt interruption. Slow recognition of the next codon, the in-frame termination codon, probably allows sufficient time for dissociation of the pep-tRNA. The exact function of the other features is still unclear.

The generality of the gene 60 bypass has recently been reinforced by a study showing that inefficient bypassing can be stimulated merely by providing a sufficient translational pause at a poorly recognized codon. During the pause pep-tRNA can dissociate from the mRNA and scan in the 3' direction in search of a matching codon. The efficiency of the bypass depends on the distance to the next codon since pep-tRNAs tend to spontaneously dissociate from the ribosome during the search.

StopGo: Termination and Reinitiation of Translation both by Non-canonical Means

Arguably, the most bizarre form of translational recoding occurs at the end of a gene encoding the 2A peptides of picornaviruses. These viruses express a polyprotein from a single ORF encoded in their genomic RNA. The various activities in that polyprotein must be separated from each other into individual polypeptides and in most cases that separation involves proteolytic cleavage of the primary translation product. 2A was originally thought to be a protease because it is required for two such events in the region encoding structural proteins of the virus capsid. Rather unlike an enzyme, though, the peptide is present at two positions immediately upstream of the site of cleavage. This structure suggested that the peptide acts stoichiometrically to induce a conformation of the polyprotein that destabilizes this bond rather than acting as a true enzyme. The putative cleavage site consists of the sequence N-Pro-Gly-Pro-C with the proposed site of cleavage being between the Gly and next Pro.

However, it now has been shown that in fact no chemical bond is ever created between these two amino acids. Rather, translation of the polyprotein proceeds until the peptidyl-tRNA^{Gly} is bound at the Gly codon. At this point, rather than continuing by transferring the peptide to the tRNA^{Pro} on the next codon, the peptide is released possibly as a result of the action of peptide release factor despite the absence of a termination codon in the A site. After release of the peptide, translation immediately resumes by decoding of the adjacent Pro codon. This reinitiation does not involve the normal machinery and the amino acid inserted is Pro rather than the normal Met. So, both the termination and reinitiation events are non-canonical and, depending on whether peptide release factors are involved, may be independent of the normal translation factors. The 2A peptide encoding gene can be inserted into foreign eukaryotic genes where it induces a StopGo event as it does in picornaviruses. The peptide does not function in bacteria suggesting that the event may require some eukaryote-specific feature of the ribosome or translation factors.

Glossary

Anhydrobiotic A state of temporary suspension of vital activities triggered by the lack of water, which allows an organism to resist long periods of drought.

Antifungal A drug that inhibits and/or destroys the growth of fungi.

Antioxidant A molecule that inhibits the oxidation of other molecules.

Appressorium An adhesive structure typical of many fungal plant pathogens, which is used to infect host plants.

Biofilm The term describes a highly organized community of microorganisms, which is associated to surfaces (including medical devices) and is enclosed within a self-produced protective extracellular matrix. They possess complex structural and functional features.

Echinocandins A class of semisynthetic lipopeptide antifungal drugs that act by inhibiting β -1,3-glucan synthesis, thereby damaging fungal cell walls.

Exponential phase The step where the microbial population reaches its highest growth rate, and the generation time is minimal. During this phase microorganisms rapidly consume the corresponding nutrients present in the culture medium.

Free radicals Atoms or group of atoms that have at least one unpaired electron and which, therefore, are unstable and highly reactive.

Fungi Eukaryotic organisms, heterotrophic that lack of chlorophyll, aerobic (rarely anaerobic). They display a mycelial structure (mycelium) with rigid cell walls. Widely distributed in nature, they act essentially as saprophytic organisms. Some fungi are opportunistic pathogens of humans, animals and plants, there are species that produce mycotoxins.

Macrophage A type of white blood cell that engulfs and digests cell debris, foreign substances, microbes, cancer cells, and anything else that does not contain the components specific of healthy body cells on its surface, in a process called phagocytosis.

Nosocomial infections Microbial infections (usually caused by opportunistic pathogens) acquired in hospitals or health care centers.

Oxidative stress The loss of the inner redox balance of an organism, affecting the ratio between the oxidants generated as a result of cellular metabolism and those of antioxidant defense systems.

Phagocytosis A type of innate immune response, during which phagocytes engulf and digest microorganisms and cell debris. It constitutes an important defense against infection.

Stationary phase A growth state in which the number of microorganism (or other mass culture parameters) does not increase. Cells in the stationary phase evolve a different metabolism to those in the exponential phase.

Thermotolerance The ability to withstand relatively warm conditions. Usually an adaptive mechanism that allows the cells to survive a lethal heat-shock, provided they are previously subjected to a high, but otherwise non-lethal growth temperature. This "adaptive tolerance" is extended to other environmental types of stress.

Trehalose A natural α -linked disaccharide formed by an α , α -1,1-glucoside bond between two α -glucose units. It plays important physiological roles in the biosphere, but is absent in mammals

Virulence The degree of pathogenicity of a microorganism expressed as the rate of morbidity/mortality, or the capacity to cause disease.

Yeasts Unicellular and (generally) uninucleate fungi, endowed with asexual reproduction through budding or fission, as well as sexual reproduction by fusion of compatible cells. Some species are able to carry out dimorphic conversion from individual cells to hyphal structures (mycelia) under certain environmental conditions. Several yeasts possess important biotechnological applications, and a few are pathogenic for humans.

Introduction: Trehalose, an Outstanding Molecule

Trehalose (α -D-glucopyranosyl α -D-glucopyranoside) is a nonreducing disaccharide composed of two glucose moieties linked by their anomeric carbons. Although three configurations are chemically feasible, (α , β -1,1-, β , β -1,1- and α , α -1,1-), only the last one has been preserved during evolution. In fact, trehalose is widely present in the biosphere, where it fulfils essential roles in a variety of prokaryotic and eukaryotic organisms, ranging from archaea, bacteria and fungi to plant and invertebrates (Argüelles, 2000; 2014;

This article is a reprint of J.-C. Argüelles, J.P. Guirao-Abad, R. Sánchez-Fresneda, Trehalose: A Crucial Molecule in the Physiology of Fungi, *Reference Module in Life Sciences*, Elsevier, 2017.

Elbein et al., 2003; Eleutherio et al., 2015). Surprisingly, however, trehalose synthesis is absent in vertebrates, including mammals, despite the fact they have conserved genes coding for trehalose-hydrolyzing enzymes (Elbein et al., 2003; Argüelles, 2014). This raises some interesting questions regarding the distinct evolutionary lineages followed by invertebrates and vertebrates. The molecule was discovered in 1832 by Wigers in rye contaminated by a fungus (very likely ergotism) and the etymology of the term “trehalose” comes from, a sweet substance secreted by several beetle and insect cocoons (“trehala manna”). Curiously, it has been suggested that trehalose might have been the “manna,” described in the Biblical *Book of Exodus* as the sweet and nutritious food promised by God to Moses. This miraculous substance was eaten by Israelites, allowing them to survive during their long journey through the desert (Richards et al., 2002).

Why, does trehalose seem to be the “chosen” natural compound, compared to other structurally similar sugars? The biological success of trehalose can be explained by its chemical structure as well as by its exclusive physical properties (summarized in Table 1). The α,α -1,1-glycosidic linkage confers a nonreducing character and makes trehalose highly resistant to both acid hydrolysis and cleavage by nonspecific glycosidases. Together with its great hydrophilicity, trehalose is more stable at a wide range of temperatures and pH (Richards et al., 2002; Argüelles, 2014). In water solutions, trehalose is able to maintain a glass state that allows the formation of permanent nonhygroscopic glasses at high temperatures and upon desiccation. Thus, trehalose can protect membranes and biological structures by replacing the water molecules during periods of dehydration, toxic exposure or freezing (Richards et al., 2002; Elbein et al., 2003; Crowe, 2007).

Metabolism of Trehalose

Several metabolic pathways have been characterized in trehalose among the archetypical organisms so far studied (Fig. 1; Scheme 1; Argüelles, 2000; Elbein et al., 2003). Notably, the prokaryotes contain more developed systems for trehalose metabolism, which would explain the ample variety of roles played by the disaccharide compared to eukaryotes. Thus, in bacteria, trehalose synthesis takes place through at least three routes (termed as OtsAB, TreS and TreYZ) (Fig. 1), all of them rendering free trehalose as end product, but differing in the substrates and enzymes involved. In turn, each pathway seems to be induced in response to specific nutritional or environmental stimuli (Elbein et al., 2003; Avonce et al., 2006; Tournu et al., 2013). However, it is quite common for them to coexist in a single bacterial species, even in several copies. In contrast, the eukaryotes have only conserved the OtsAB “orthologous” pathway (named as TPS/TPP) (Avonce et al., 2006; Tournu et al., 2013; Argüelles, 2014). The corresponding genes coding for enzymes involved in trehalose metabolism have been cloned in a large number of bacteria and fungi. It is worth noting that the only reported archaeal trehalose synthase complex matches the yeast mechanism (Zaparty et al., 2013).

Biosynthesis

In yeasts and fungi, trehalose is synthesized in two enzymatic sequential steps, for which the genes responsible have been cloned and sequenced in several species (Scheme 1): (1) the transfer of a glucosyl unit from UDP-glucose to glucose-6P leads to the formation of trehalose-6P, a reaction catalyzed by a Mg-dependent trehalose synthase (TPS1) (Cabib and Leloir, 1958; Zaragoza et al., 1998; Bell et al., 1998); (2) subsequent dephosphorylation by a specific trehalose phosphatase (TPS2) gives rise to free trehalose, the physiological compound stored inside the cells (Van Dijck et al., 2002; Zaragoza et al., 2002). An alternative pathway using ADP-glucose as glucosyl donor has been characterized in some bacteria, but, to our knowledge, not yet in fungi.

Trehalose-biosynthesizing enzymes have been extensively studied in budding yeasts (*Saccharomyces cerevisiae*), where Tps1p and Tps2p are integrated in a single complex with two other proteins, named Tls1 and Tls3, which lack catalytic activity and essentially contribute to stabilizing this complex. Single deletion of either Tls1 or Tps3 has no significant effect on trehalose biosynthesis, but a double disruption causes a 50% decrease in the endogenous content of trehalose and modifies the effect of phosphate on trehalose synthase activity (Bell et al., 1998; Gancedo and Flores, 2004).

Table 1 A survey of the main features, physiological roles and applications displayed by the nonreducing disaccharide trehalose (*O*- α , α -D-glucopyranosyl-[1 $\rightarrow$ 1]- α -D-glucopyranoside) in the biosphere.

Physical properties	Physiological roles	Biotechnological applications
Nonreducing sugar	Energy and carbon reserve/source	Therapeutic compound
High hydrophilicity	Cell protectant against stress	Antifungal target
Internal chemical stability	Stabilizer of membranes and proteins	Cryoprotectant
Unable to form hygroscopic glasses	Component of the bacterial cell wall	Prophylactic and stabilizer
Absence of inner hydrogen bonds	Major compatible solute	Industrial fermentation
Resistant to acid hydrolysis	Sensing compound	Food sweetener
Elevated melting point	Metabolic regulator	Nutritional supplement
	Virulence factor	Cosmetic additive

Note: For other specific details, see the text

Fig. 1 The established metabolic pathways involved in trehalose biosynthesis in the biosphere. The corresponding organisms are indicated within squares. To date, the annotated genomes of vertebrates lack any functional trehalose synthase/phosphatase gene. Furthermore, no alternative route for trehalose interconversion or isomerization is known. The hydrolysis of trehalose by trehalases releases two molecules of glucose. Partially adapted from Argüelles (2014). For other specific details, see the text.

Hydrolysis

In contrast, trehalose degradation in eukaryotes is essentially confined to the enzyme trehalase (E.C. 3.2.1.28), an α -glucosidase rigorously specific for trehalose that cleaves off the α , α -1,1-glycosidic linkage to yield two molecules of D-glucose (Scheme 1). There are two exceptions to this universal hydrolytic mechanism:

Trehalose phosphorylase: this enzyme carries out the phosphorylolytic cleavage of trehalose into glucose-1P and glucose, a reversible reaction which, in vivo, tends toward the degradative step (Scheme 1). Among fungi, this activity has mainly been described in basidiomycetes (eg, *Schizophyllum*, *Agaricus* or *Flammulina* spp.).

Phosphotrehalase: it catalyzes the conversion of trehalose-6P into glucose and glucose-6P (Scheme 1). Phosphotrehalase has mainly been reported in prokaryotes and in a single strain of the yeast *Pichia fermentans*, which throws doubt on its existence in fungi (Argüelles, 2000; Tournu et al., 2013).

Regarding trehalase activity, yeasts and filamentous fungi usually contain two different types of this α -glucosidase, distinguishable on the basis of their cellular location, amino acid sequence, tridimensional configuration, catalytic parameters, physiological roles and regulatory mechanisms. They are normally called neutral (Nth1p/Ntc1p) and acid (Ath1p/Atc1p) trehalases (Thevelein, 1984, 1996). Despite their very low degree of similarity, the two enzymes are rigorously specific for trehalose as sole substrate, a specificity based on an equivalent folding structure in the active center and an identical catalytic anomeric inversion mechanism. Notably, in the yeast *Candida parapsilosis*, the homozygous disruption of both trehalases does not cause lethality (Sánchez-Fresneda et al., 2015).

On the other hand, although still not fully characterized, another kind of trehalases, identified in some thermophilic fungi, displays a different pattern of biochemical parameters, including an optimum temperature of 50–60°C. Their biological functions remain unknown, but the high thermal stability makes them a promising source of soluble trehalases for both research and biotechnological purposes (Cardello et al., 1994; Bharadwaj and Maheswari, 1999).

Principal Physiological Roles of Trehalose in Fungi

Reserve Carbohydrate and Stress Protective Molecule

For many years, trehalose in fungi has been considered as a carbon and energy reserve compound, because it is largely stored by starved or resting vegetative cells as well as by dormant and reproductive structures (spores, sclerotia, germlings, myxoamoebae) (Wiemken, 1990; Thevelein, 1996; Argüelles, 2000; Elbein et al., 2003), where it may be found in high concentrations (up to 15–20% of dry cell weight) (Fig. 2). The rapid mobilization of trehalose is closely correlated with the resumption of active growth and spore germination. Nevertheless, this role is somewhat controversial (Thevelein, 1984, 1996; Wiemken, 1990; Argüelles, 2000;

B-2) Trehalose phosphorylase

B-3) Phosphotrehalase

Scheme 1 General pathways involved in trehalose biosynthesis (A) and hydrolysis (B) elucidated in prototypical models of fungi.

Elbein et al., 2003), since a “genuine” reserve compound is only synthesized when the exogenous energy exceeds the cellular needs for growth and biosynthesis, and is degraded when cell viability is threatened. However, trehalose biosynthesis contradicts this rule, and is predominantly synthesized at the onset of reduced growth periods, not when there is an excess of exogenous energy. Furthermore, trehalose storage remains intact under resting (ie, spores) or starvation (ie, stationary phase) conditions, and the amount of glucose released from intracellular trehalose mobilization accounts for a minimal percentage of energy compared to that provided by the classical reserve carbohydrate, namely glycogen (Wiemken, 1990; Thevelein, 1996; Argüelles, 2000).

Fig. 2 Main environmental and physiological conditions able to induce trehalose accumulation in Fungi.

More convincing is the evidence supporting trehalose as an efficient protector of cellular integrity against drastic nutritional or environmental stresses (eg, nutrient starvation, high temperatures, osmotic pressures, oxidant agents, heavy metals, anhydrobiosis, xenobiotics, etc., Fig. 2). This phenomenon has been broadly characterized in numerous fungal species, which are able to respond to these sudden perturbations by the rapid synthesis of huge amounts of trehalose, providing them with the potential to withstand these challenges for long periods (Wiemken, 1990; Argüelles, 2000; Richards et al., 2002; Crowe, 2007). The exclusive physical features of trehalose described above (Table 1), together with the absence of internal hydrogen bonds in the molecule, are sufficient to explain the principal role exerted by the disaccharide as stress metabolite (Table 1).

A strong correlation between trehalose content and resistance to osmotic stress was unequivocally demonstrated in many prokaryotic and eukaryotic organisms (Strom and Kaasen, 1993; Thevelein, 1996; Elbein et al., 2003). Indeed, in some bacteria, the enzymes involved in trehalose metabolism are specifically regulated by osmotic shock (eg, the *otsA*, *otsB* and *treA* genes in *Escherichia coli*). In many fungi, large amounts of trehalose are accumulated in response to an increase in external osmolarity (Argüelles, 2000, 2014; Elbein et al., 2003). It is worth mentioning the biological significance of this mechanism in anhydrobiotic organisms, which encompass not only fungi but also plants, insects and microscopic animals (rotifers, nematodes or crustaceans). These life forms are able to survive in virtually dehydrated ecosystems because they accumulate substantial concentrations of endogenous trehalose. Furthermore, during the desiccated state the metabolic activity of these cells is virtually negligible, but they can endure adverse conditions like drought, heat, frost or radiations for many years (Wiemken, 1990; Thevelein, 1996; Eleutherio et al., 2015). The water replacement mechanism and the formation of nonhygroscopic glasses by trehalose, together with its elevated chemical stability may account for this process, since trehalose preserves both membranes and proteins in a physical state resembling that associated with fully hydrated conditions (Elbein et al., 2003; Crowe, 2007). Upon rehydration, the “metabolic resurrection” of anhydrobiotic organisms is accompanied by simultaneous rapid trehalose mobilization.

An important corollary of the above is the pivotal role of trehalose as a molecular chaperone in the efficient refolding of proteins partially denatured after severe heat-shock exposure and stabilizing proteins at high temperatures (Singer and Lindquist, 1998; Crowe, 2007). Later on, trehalose must be quickly hydrolyzed in order to ensure proper thermal-stress recovery (Singer and Lindquist, 1998). The resting states and dormant forms of biological cycles in fungi (ie, stationary phase and spores) are thermotolerant conditions and positively correlate with trehalose storage. These conditions can be mimicked in the laboratory through the “acquired thermotolerance” approach, a mechanism that, in yeasts, allows actively growing cells (25–30°C) to survive subsequent exposure to potentially lethal temperatures (<50°C), provided the cultures are previously subjected to a permissive heat-shock (37–42°C), which induces an enormous accumulation of intracellular trehalose (Singer and Lindquist, 1998). Interestingly, trehalose accumulation is also induced upon cold exposure and is essential for the maintenance of cell viability at low temperatures. This feature explains its useful biotechnological application as cryoprotectant in the food, cosmetics and pharmaceutical industries (see below; Table 1; Ohtake and Wang, 2011; Argüelles, 2014).

The physiological protective function of trehalose can be widened to include the so-called “core stress response,” which has been unequivocally demonstrated in yeasts. By means of this mechanism, exponential cells (preferentially) can withstand the exposure to a set of lethal injuries, following stimulation with gentle doses of a non-related stress. For instance, mild upshifts from 28–30 to 37–42°C, increase the degree of cell survival against a further oxidative treatment with 50 mM H₂O₂ (Argüelles, 2000, 2014). Of course, this core response is very complex and trehalose is only part of a global defensive response that includes many components, such as transcription factors, regulatory proteins, detoxifying enzymes and small molecules like glutathione or α -tocopherol. Remarkably, the stress-induced trehalose synthesis in yeasts, as well as its storage as compatible solute in bacteria,

provides consistent support for its protective role in unicellular organisms that must confront the challenging nutritional and environmental conditions (Argüelles, 2014).

Oxidative Stress Protector in Pathogenic Fungi

At this point, we considered convenient to make a few pertinent remarks on the fungal defensive framework against stress. Among potential fungal pathogens in humans and animals, trehalose appears to be mainly related with a specific protection against oxidative stress, a mechanism connected with virulence and essential to withstand the endogenous reactive oxygen species (ROS) produced by phagocytic cells in the course in vivo tissue colonization by the fungus (Martínez-Esparza et al., 2007, 2009). Thus, in *Candida albicans* massive endogenous trehalose synthesis occurs in response to external oxidants or during macrophage ingestion, rather than in the face of other environmental challenges. Furthermore, mutants disrupted in trehalose biosynthesis (*tps1Δ* and *tps2Δ*) show high sensitivity to exogenous oxidants and phagocytosis by murine macrophages (Martínez-Esparza et al., 2007, 2009). In turn, the perturbation of trehalose homeostasis increases the susceptibility of *Aspergillus nidulans* to oxidative stress (Fillinger et al., 2001). In *Cryptococcus* spp., the trehalose metabolism plays a key role in regulating sporulation and further spore viability (*Cryptococcus neoformans*), while trehalose alterations cause defects in melanin synthesis, capsule production, mating and the cell wall architecture (*Cryptococcus gatti*) (Petzold et al., 2006; Botts et al., 2014).

Antifungal Target

Compared with the large number of pathogenic bacteria, infective fungi are scarce and generally opportunistic, most being associated with septicemic mycosis, infections secondary to a previous debilitating illness (Pfaller and Diekema, 2010). For these reasons, antifungal therapy has received less attention than its antibacterial equivalent. However, this picture has dramatically changed in the last two decades, in which the morbidity and mortality caused by opportunistic fungi have strikingly increased, particularly among the ageing and immunocompromised population (including AIDS patients, transplant recipients, neonates or those undergoing intensive chemotherapy). At present, *C. albicans* represents the fourth cause of nosocomial infections recorded in US hospitals.

The biochemical and genetic data available on pathogenic yeasts has led to the enzymes involved in the trehalose metabolism to be proposed as potential targets for the design of new antifungals (Fig. 2). The most important evidence in this respect is: (1) the nonreducing sugar is present in bacteria, fungi, plants and invertebrates, but is absent in mammals, a finding that favours its clinical application with high selective toxicity (Richards et al., 2002; Elbein et al., 2003; Argüelles, 2014); (2) trehalose accumulation seems to be a protective mechanism of pathogenic fungi during in vivo infection (Martínez-Esparza et al., 2007, 2009); and (3) the genes coding for trehalose-6P-synthase (*TPS1*) and trehalose-6P-phosphatase (*TPS2*) are determinants of virulence; and the corresponding *tps1Δ* and *tps2Δ* null mutants show diminished resistance to phagocytosis mediated by macrophages (Zaragoza et al., 1998, 2002; Van Dijk et al., 2002; Martínez-Esparza et al., 2007, 2009). Interestingly, echinocandins, which act as potent inhibitors of cell wall glucan synthases, are widely used as antifungals in clinical practice (Denning, 2003). Accordingly, a *C. albicans tps1Δ* mutant show alterations in the cell wall structure, and the acid trehalase is located in the external cell wall in some pathogenic yeasts (Pedreño et al., 2004; Martínez-Esparza et al., 2007; Sánchez-Fresneda et al., 2015). Furthermore, Amphotericin B significantly induces trehalose synthesis in *C. albicans*, the *tps1Δ* mutant being very sensitivity to the polyene (González-Parraga et al., 2011). Therefore, trehalose might be a promising avenue in the search for new antifungal chemotherapeutic agents.

Virulence Factor

The hypothetical role of trehalose as a determinant of virulence is somewhat interconnected with the rationale documented in the above two sections. Data in favor of this proposal have mainly been obtained using in situ genetic approaches in the prevalent pathogenic yeast *C. albicans*, by means of single disruption of the trehalose-biosynthesizing genes *TPS1* and *TPS2*. To the best of our knowledge, a homozygous double *TPS1/TPS2* disruption has not been achieved yet. In addition to defects in the cell wall architecture, a *C. albicans tps1Δ* mutant displays high vulnerability to oxidative stress and diminished resistance to phagocytosis by macrophages stimulated with interferon- γ (Martínez-Esparza et al., 2007). The *tps2Δ* mutant shares similar sensitivity to oxidants and macrophage killing, but the phagocytosis triggers a proinflammatory response with the release of TNF- α (Martínez-Esparza et al., 2009). Furthermore, *tps2Δ* cells exhibit a pleiotropic phenotype that includes deficient growth at high temperatures (42°C), greater permeability and cell aggregation in resting cultures (Martínez-Esparza et al., 2009).

Regarding trehalose hydrolysis, the lack of a functional neutral trehalase (Ntc1p) does not seem to play any relevant role in dimorphic conversion or pathogenicity (Eck et al., 1997). However, disruption of the *ATC1* gene encoding the acid trehalase activity hinders the cell's capacity to use exogenous trehalase and impairs the infectivity and degree of hypha formation, crucial events during host tissue invasion (Pedreño et al., 2004; Sánchez-Fresneda et al., 2015). Although not yet performed in *C. albicans*, the homozygous deletion of *ATC1* and *NTC1* in *C. parapsilosis* is not lethal (Sánchez-Fresneda et al., 2015).

Trehalose also participates in the pathobiology of other relevant opportunistic fungal pathogens, namely *Aspergillus* spp., which is a frequent cause of pulmonary diseases, and *Cryptococcus* spp., that infects mainly HIV patients and produces a characteristic meningoencephalitis. In *Aspergillus fumigatus*, a mutant deficient in T-6P phosphatase activity shows acute morphological defects, related to asexual reproduction, and is avirulent in two distinct models of invasive pulmonary aspergillosis (Puttikamonkul et al.,

2010). Surprisingly, the double *ΔtpsAB* strain lacking a functional trehalose synthase complex was hypervirulent in a murine test, a perturbation also associated with susceptibility to oxidative stress, alterations in the cell wall and resistance to phagocytosis (Al-Bader et al., 2010). In *C. neoformans*, the orthologous *tps1* mutant unable to synthesize trehalose showed attenuated virulence and sensitivity to exogenous oxidants compared to *tps2* (T-6P phosphatase) and *nth1* (neutral trehalase) mutants (Petzold et al., 2006). In contrast, deletion of *NTH2* gene, which encodes a previously uncharacterized secreted trehalase, caused hypervirulence in a murine model (Botts et al., 2014).

Nevertheless, the strong evidence concerning the crucial implication of trehalose metabolism in fungal virulence was not gathered from human pathogens, but comes from the elegant work performed with the phytopathogenic rice blast fungus *Magnaporthe grisea* (Foster et al., 2003). The inability to synthesize trehalose in a *tps1Δ* mutant gives rise to impaired sporulation and attenuated pathogenicity. In addition, the appressoria developed by the fungus showed poor development and decreased cuticle penetration (Foster et al., 2003). The prevention of trehalose mobilization by disruption of the *NTH1* gene, which encodes neutral trehalase activity, also reduced *M. grisea* infectivity due to the lower capacity to colonize plant tissue (Foster et al., 2003). More relevant, Tps1p is a key regulatory molecule that integrates control of glucose-6P metabolism and nitrogen source utilization, through direct regulation of the pentose phosphate pathway, the generation of NADPH and the nitrate reductase activity in *M. grisea* (Wilson et al., 2010). Together, these results correlate the pivotal role played by Tps1p in fungal virulence and the integration of carbon and nitrogen metabolism.

Regulatory Signal

Research into trehalose in plants reflects the spectacular increase in our knowledge of this singular molecule gained during the last 30 years. For a long time, trehalose was considered a rare sugar confined to the so-called “resurrection” plants. Nowadays, however, the current picture points to a very complex system that encompasses a large number of genes involved in trehalose metabolism, with distinct degrees of functionality (Eastmond and Graham, 2003). Notably, the intermediate trehalose-6P acts as a key regulator of important physiological and developmental processes in plants, such as carbohydrate utilization, starch mobilization in leaves, embryo maturation, and flower and young tissue development (Eastmond and Graham, 2003).

In the case of yeasts and filamentous fungi, an unexpected regulatory role for glycolysis by trehalose emerged from the unpredictable observation that a set of mutants deficient in *S. cerevisiae* trehalose-6P-synthase activity (*tps1*, *fdp1*, *cif1*, *byp1* or *ggs1*) were unable to grow on glucose, although the glycolytic enzymes assayed in vitro remained fully active (Gancedo and Flores, 2004). In contrast, deletion of the *TPS2* gene did not cause this metabolic defect. When the *tps1* mutants were grown on non-fermentable carbon sources, the accumulation of hexose phosphates was concomitant with a marked drop in the internal ATP content, a defect explained by an imbalance between the rates of the initial ATP-consuming steps of glycolysis and those regenerating it after the glyceraldehyde 3-P dehydrogenase reaction (Gancedo and Flores, 2004). Several hypotheses have been advanced in this respect. (1) Tps1p is a direct regulator of glucose transport and phosphorylation through its alliance with a sugar carrier and hexokinase in a postulated “General glucose-sensing complex” (Thevelein and Hohmann, 1995; Gancedo and Flores, 2004); (2) Trehalose synthesis serves as a metabolic buffer when glycolysis overflows by channeling the excess of glucose-6P (precursor of trehalose synthesis), allowing the recovery of free phosphate, which is required for the mentioned glyceraldehyde-3P dehydrogenase reaction; (3) Biochemical results support the competitive inhibition of hexokinase by T-6P (Blázquez et al., 1993). Thus, this intermediate, whose accumulation might be toxic, has emerged as new key regulator of yeast glycolysis (Gancedo and Flores, 2004).

It is worth noting that in *M. grisea* (see above), *C. albicans* and *Kluyveromyces lactis* a functional Tps1p activity is required for normal glycolytic flux and, accordingly, a *Δtps1* mutant cannot grow on glucose or fermentable sugars, displaying thereby a serious metabolic imbalance. Although the molecular data are still inconclusive, trehalose hydrolysis in fungi may be considered a physiological signal from the transition from resting states to full active growth (in accordance with the abundant evidence documented above).

Final Comments and Perspectives

Since its discovery in 1832, investigation into the biological significance of trehalose has come a long way. Of the wide number of physiological roles played by trehalose, the most relevant appear to be confined to the specific systems analyzed. Thus, in bacteria, trehalose serves as carbon source, compatible solute or structural component (the “cord factor” in mycobacteria). In insects, trehalose is considered the main biofuel present in the circulatory fluid (hemolymph), where it represents up to the 20% of the total carbohydrate pool in certain stages of development. Intriguingly, vertebrates do not have the ability to synthesize trehalose, which raises some interesting questions on its evolutionary phylogeny. Within fungi, yeasts could be considered the simplest eukaryotes and, therefore, a good model for biological studies. The extensive experimental work carried out on trehalose metabolism in several yeasts has revealed the specific functions described here, many of them also present in multicellular organisms. Finally, although beyond the scope of this article, mention must be made of the increasing number of biotechnological, nutritional and therapeutic possibilities of trehalose, some of them already in commercial use. As a conspicuous example, we would like to emphasize the exciting new findings on the important role played by trehalose as an inducer of autophagy via an

mTOR-independent pathway, which is currently used to combat the formation of amyloid plaques, a critical symptom of Huntington's, Parkinson's, Alzheimer's diseases and other severe neurodegenerative disorders.

Glossary

African trypanosomiasis (sleeping sickness) An illness endemic in large areas of sub-Saharan Africa, which is transmitted by tsetse flies. *Trypanosoma brucei gambiense* is the cause of West African or gambiense trypanosomiasis, and *Trypanosoma brucei rhodesiense* is the cause of East African or rhodesiense trypanosomiasis.

Amastigote The life-cycle stage of *Trypanosoma cruzi* that multiplies intracellularly.

American trypanosomiasis (Chagas disease) An illness endemic to all non-Caribbean countries in Latin America, which is caused by the protozoan parasite *Trypanosoma cruzi* and is usually transmitted by triatomine insects.

Blood-form trypomastigote The life-cycle stage of both American and African trypanosomiasis found in the blood, cerebrospinal fluid, and other extracellular spaces.

Epimastigote The multiplying life-cycle stage of trypanosomes found in insect vectors.

Metacyclic trypomastigote The life-cycle stage of trypanosomes that develops in insect vectors and is infective for humans and other mammals.

Trypanosomiasis A group of diverse diseases caused by members of the genus *Trypanosoma*, which are hemoflagellate protozoa.

Abbreviations

CNS	Central nervous system
DFMO	Difluoromethylornithine
ELISA	Enzyme-linked immunosorbent assay
ES	Expression site
ESAG	ES-associated gene
Hsp70	Heat shock protein 70
ODC	Ornithine decarboxylase
PARP	Procyclic acid-rich protein
PCR	Polymerase chain reaction
RBBB	Right bundle branch block
VSG	Variant surface glycoprotein

Trypanosoma cruzi

Trypanosoma cruzi is the protozoan parasite that causes American trypanosomiasis or Chagas disease. It is epizootic and endemic in all Latin American countries outside the Caribbean, including Mexico, and it is an important cause of chronic heart and digestive diseases in these nations. Studies of autopsied Native American mummies indicate that Chagas disease in humans dates back to the pre-Colombian era, and given the widespread distribution of mammalian reservoirs (e.g., opossums, armadillos, and many dozens of others) it is reasonable to assume that humans have been infected since they first invaded enzootic regions roughly 14,000 years ago. Seroepidemiologic and clinical studies indicate that approximately 8 million persons are chronically infected with *T. cruzi* in endemic countries and roughly 20,000 die annually as a result of the infection. Several autochthonous cases of *T. cruzi* infection have been reported in the United States since 1955, and small numbers of infected blood donors who have not visited endemic countries have been identified since serologic screening of the US blood supply. Naturally infected dogs as well as a wide variety of

wild mammals have also been described in the southern and southwestern United States, and infected insect vectors have been found in these areas as well.

Transmission

In endemic areas transmission is most common among the rural poor whose dwellings become infested with infected vectors due to the proximity of sylvatic reservoirs. Vector-borne transmission of *T. cruzi* is contaminative, since the infective parasites are in the excreta of the insects. During a blood meal, insect feces containing metacyclic trypomastigotes by chance find their way onto mucosal surfaces, the conjunctivas, or breaks in the skin. There they enter susceptible cells of the new host and establish infection. Control programs directed at decreasing contact with insect vectors through housing improvement, insecticide spraying, and education have met with considerable success in many endemic areas. The transmission of *T. cruzi* by blood transfusion historically has been the second most important mode of spread of the parasite. This was a major public health problem in many endemic regions, but its importance has been reduced markedly in recent years through widespread implementation of serologic screening of donated blood. Several cases of transfusion-associated transmission of *T. cruzi* have been reported in the United States, Canada and European countries, resulting from the transfusion of blood donated by asymptomatic *T. cruzi*-infected immigrants from Latin America. Other modes of transmission include congenital, organ transplantation, laboratory accidents, ingestion of contaminated food or drink, and breast feeding.

Organism and Life Cycle

T. cruzi has a complex life cycle in which four morphologically and biochemically distinct forms exist (Fig. 1). In mammalian hosts, there are two forms: extracellular nondividing trypomastigotes (blood forms) (Figs. 2 and 3), and intracellular dividing amastigotes (Figs. 4 and 5). During a blood meal, the insect vectors ingest blood forms, which then transform into epimastigotes in the midgut. After 3–4 weeks, infective but nondividing metacyclic trypomastigotes are present in the hindgut of the vector. These forms are then deposited with the excreta of the vector during subsequent blood meals. Transmission occurs to a new mammalian host when these infective parasites contaminate susceptible tissues. The infective trypomastigotes parasitize cells by direct penetration or through phagocytosis, and then transform into amastigotes.

The mechanisms by which the trypomastigotes gain entry into host cells are not entirely understood. Although phagocytosis was the first endocytic mechanism described to be used by *T. cruzi*, other mechanisms such as clathrin-mediated endocytosis, caveolar-dependent, and lipid raft-dependent endocytosis macropinocytosis seem to be involved. Studies have implicated the enzyme *trans*-sialidase in this process. Penetrin, another parasite molecule, binds to heparin sulfate receptors on nonphagocytic host cells, thereby promoting adhesion and subsequent parasite invasion. There several host cell receptors that have been described which aide in the entry of the parasite into cells.

Once in the cytoplasm of the host cells, amastigotes (Figs. 4 and 5) undergo binary fission and as sizable numbers accumulate the cell is overwhelmed and transformation to trypomastigotes occurs. Although any nucleated mammalian cell can be invaded by

Fig. 1 Life stage forms of *Trypanosoma cruzi*. Note the kinetoplasts; see Fig. 5 for the ultrastructure of this organelle. The trypomastigotes measure 15–20 μm in length, the epimastigotes measure 20 μm length, and the amastigotes measure 3–4 μm in diameter.

Fig. 4 Giemsa-stained endothelial cells infected with *Trypanosoma cruzi*. Note the numerous amastigotes.

this parasite cells of the reticuloendothelial, nervous and muscle systems appears to be favored. In addition, recent evidence suggests that adipose tissue and adipocytes are readily invaded by trypomastigotes.

The parasitized cells eventually rupture, releasing amastigotes and trypomastigotes that infect adjacent cells and importantly trypomastigotes disseminate through the lymphatics and the bloodstream, ultimately infecting a wide variety of tissues, including cardiac and skeletal muscles, as well as cells of the reticuloendothelial and nervous systems. In the parasitophorous vacuole,

Fig. 5 Transmission electron micrograph of parasitized myoblast cell line. Note the amastigotes in the cytoplasm and their prominent disk-shaped kinetoplasts.

amastigotes synthesize a hemolysin that lyses the vacuolar membrane, thus allowing the parasite to escape the cytotoxic mechanism of the cell. Both cell necrosis and apoptosis have been reported to be associated with *T. cruzi* infection.

The chromosomal complement of *T. cruzi* is approximately 50 Mb or roughly 10 times the amount of DNA found in *E. coli*. Pulse-field gel electrophoresis reveals at least 20, and as many as 40, discrete chromosomal bands, ranging in size from 200 to 2000 kb. *T. cruzi* molecular karyotypes are somewhat strain-dependent (i.e., the reference strain CL/Brener contains approximately 60–80 Mb DNA). Among characterized strains, there appears to be only one that contains minichromosomes, in sharp contrast to *T. brucei*. The genome of *T. cruzi* appears to be diploid in all stages. Homologous chromosomes, however, can differ markedly in size, and chromosomes containing conserved linkage groups can vary extensively in size among isolates. *T. cruzi* exhibits significant polymorphism at a number of characterized alleles, far in excess of that seen in higher eukaryotes. It appears that multiplication of *T. cruzi* is exclusively, or nearly exclusively, clonal without any evidence of a sexual stage. Starting back in the 1980s, numerous genes of *T. cruzi* were cloned and characterized, and the complete DNA sequencing of the CL Brener strain of *T. cruzi* and several other strains has been completed (Genome data can be found at <http://tritrypdb.org/tritrypdb/>).

Many *T. cruzi* genes are arranged in tandem arrays of nearly identical copies, as is the case with GAPDH, histone H1 and heat shock protein (Hsp70). Importantly, *T. cruzi* genes lack introns and all mature mRNAs have a highly conserved 5' cap (spliced leader) that is added to pre-mRNAs by *trans*-splicing. *T. cruzi* mRNAs contain poly-A tails, but there is no highly conserved poly-A addition site consensus sequence, as is the case with other eukaryotes. The classification of *T. cruzi* strains has been accomplished by a variety of methods including isoenzyme differences (zymodemes), restriction endonuclease digest of kinetoplast DNA (schizodemes), and sequencing of noncoding segments of rRNA genes. There is considerable correlation among the groupings determined by the various approaches. These observations are consistent with the concept that *T. cruzi* consists of many clonal lineages with little sexual recombination. Moreover, the rRNA sequence data also suggest that the clonal lineages fall into two main branches (*T. cruzi* I and *T. cruzi* II) with a very ancient split between them. Assuming a constancy of the molecular clock, the divergence appears to have occurred contemporaneously with the divergence of reptiles and amphibians, which predated the first mammals.

Analyses of the *T. cruzi* CL Brener strain have revealed that the diploid genome contains a predicted 22,570 proteins, of which 12,570 represent allelic pairs. More than half of the genome consists of repeated sequences, such as retrotransposons and genes for large families of surface molecules, including *trans*-sialidases gp85 super family, mucins, gp63s, and a large novel family (>1300 copies) of mucin-associated surface protein genes. Analyses of the *T. cruzi*, *T. brucei*, and *Leishmania major* genomes imply differences from other eukaryotes in DNA repair and initiation of replication and reflect their unusual mitochondrial DNA, which may offer targets for intervention. Proteomic analysis of the four life-cycle stages of *T. cruzi* discovered that peptide mapping to 2784 proteins in 1168 protein groups from the annotated *T. cruzi* genome were identified across all stages. The different parasite stages use different energy sources depending on the host in which they are found—histidine for stages in the insect vectors and fatty acids by trypomastigotes and amastigotes in the mammalian hosts. With the completion of *T. cruzi* genome, genomic information speeds up researches in drug-discovery, vaccine development, diagnostic markers and pathogenesis.

Epizootiology and Epidemiology

T. cruzi is found only in the southern United States, Mexico, and the nations of Central and South America. There is no Chagas disease on the Caribbean Islands. Infection with this parasite is a zoonosis and the involvement of humans in the life cycle

essentially has nothing to do with the perpetuation of the parasite in nature. The parasite primarily infects both wild and domestic mammals as well as insects. The triatomine insect vectors of *T. cruzi* are distributed from the southern United States to central Argentina. Transmission of the parasite typically occurs among infected vectors and nonhuman mammalian hosts in hollow logs, palm trees, burrows, and other animal shelters. A large number of insect vectors can also be found near houses in piles of roof tiles, wood, and vegetation. *T. cruzi* has been found in more than 100 species of domestic and wild mammals, in a range similar to that of its insect vectors. Opossums, nonhuman primates, wood rats, armadillos, raccoons, dogs, and cats all are typical hosts, but *T. cruzi* is not a problem in livestock.

Nontypical hosts, such as polar bears, can become infected when held in zoos in areas in which *T. cruzi* is enzootic. This lack of species-specificity, combined with the fact that infected mammalian hosts have life-long parasitemias, results in an enormous domestic and sylvatic reservoir in enzootic areas. Humans have become part of the cycle of *T. cruzi* transmission as farmers and ranchers open new lands in enzootic areas. When this development takes place, the vectors, known variously as the “kissing bug” or “assassin bug” (e.g., *Rhodnius prolixus*, *Triatoma infestans*, *Panstrongylus megistus* and many other species) invade the nooks and crannies of the primitive wood, mudwalled, and stone houses that are typical of rural Latin America. In this manner, the vectors become domiciliary, establishing a cycle of transmission involving humans and peri-domestic mammals that is independent of the sylvatic cycle. Historically, Chagas disease has been an infection of poor people living in rural environments. However, over the decades an enormous number of *T. cruzi*-infected people have migrated to cities, thus urbanizing the disease and, prior to the initiation of serologic screening of donated blood, resulting in its frequent transmission by transfusion.

The epidemiology of *T. cruzi* infection has improved markedly in many the endemic countries as vector and blood-bank control programs have been implemented. A major international vector eradication program in the “Southern Cone” countries of South America has provided the framework for much of this progress. To date Uruguay (1997), Chile (1999), and Brazil (2006) have been declared free of transmission. In Argentina the rate of transmission is a fraction of what it was 25–30 years ago, and substantial progress has been achieved in Paraguay and Bolivia. Similar programs have been implemented in the Andean nations and in Central America. The obstacles hindering the elimination of *T. cruzi* transmission to humans are economic and political, and no technological breakthroughs are necessary for overall control of the problem.

Approximately 30% of people who harbor *T. cruzi* chronically will develop associated cardiac or gastrointestinal symptoms. In the past, the high frequency of sudden death among young adults in some areas was attributed to rhythm disturbances due to chronic Chagas disease and in one highly endemic area of Brazil, chagasic cardiac disease was found to be the most frequent cause of death in young adults. There is considerable geographic variation in the relative prevalence of cardiac and gastrointestinal disease in patients with chronic *T. cruzi* infection. It is not known if this variable clinical expression is caused primarily by parasite strain or host factors. In this regard, studies have implicated host genetic factors as important variables in host response to infection.

The number of people in the United States with chronic *T. cruzi* infections has increased substantially in recent decades. Current estimates put the number of immigrants from Chagas-endemic living in the United States at 13 million and at least 300,000 cases of chronic Chagas disease. Their presence creates a risk of transfusion-associated transmission *T. cruzi* here, and seven such cases have been reported in the United States, Canada and European countries. Almost all the reported cases occurred in immunocompromised patients in whom the diagnosis of *T. cruzi* was made because the transfusion recipients became severely ill. This suggests that additional cases have occurred in immunocompetent patients and have gone unnoticed because they were more able to control the acute infection. However, this risk has been essentially eliminated by serologic screening of blood donated here and the confirmed prevalence among donors is about 1 in 29,000. Moreover, transmission of *T. cruzi* through organ transplantation has been reported in the United States. In a series of 32 transplant recipients in the United States who unintentionally received organs from 14 *T. cruzi* seropositive donors from 2001 to 2011, transmission was confirmed in nine recipients.

Clinical Manifestations

Acute Chagas disease

Seroepidemiologic studies in endemic areas indicate that most seropositive patients have no recollection of having had acute Chagas disease and do not carry a specific diagnosis. This results from the generally mild nature of acute Chagas disease, as well as from the fact that the persons most at risk for acquiring *T. cruzi* infection have little access to medical care. Some infected persons may develop severe symptoms after an incubation period of 7–14 days. This has been documented with vector-borne infection as well as infections acquired by blood transfusions or laboratory accidents. Signs and symptoms can include fever, chills, nausea, vomiting, rash, diarrhea, and meningeal irritation. A chagoma, a raised inflammatory lesion at the site of parasite entry, Romana’s sign (unilateral periorbital edema), conjunctivitis, lymphadenopathy, and hepatosplenomegaly have all been described in patients with acute Chagas disease. Laboratory abnormalities can include anemia, thrombocytopenia, and elevated liver and cardiac enzymes. The diagnosis of acute Chagas disease is primarily parasitologic, as motile trypomastigotes often can be found in blood and cerebrospinal fluid. Serologic tests for parasite-specific IgG are often negative during this stage, and assays for IgM have not been standardized and are not widely available. During the acute phase of the illness, asynchronous cycles of parasite multiplication, cell destruction, and infection of new cells occur. Myocarditis and cardiomegaly, sometimes associated with congestive heart failure, are present in some patients and may be more common than was previously appreciated. The appearance of arrhythmias, heart block, or congestive heart failure in the setting of acute *T. cruzi* infection is poor prognostic indicators. It is not known if the severity of acute Chagas disease is related to the likelihood of development years later of the cardiac and gastrointestinal manifestations of chronic symptomatic Chagas disease. A small percentage of acutely infected patients, often children, die of acute myocarditis or meningoencephalitis. As antibodies appear, the parasitemia wanes, and almost all infected persons resolve the acute phase of the

illness in 2–4 months, but remain infected for life. These patients then enter the indeterminate phase of the illness, which is characterized by a lack of symptoms, easily detectable antibodies to a variety of *T. cruzi* antigens, and low parasitemias. Congenital Chagas disease is another example of acute infection. It occurs in about 5% of infants born to mothers with chronic *T. cruzi* infections. These babies are most often asymptomatic but can present with fever, jaundice, and occasionally seizures, and may be difficult to distinguish from infants with other congenital infections such as toxoplasmosis. Children with congenital disease also may have cardiac and gastrointestinal manifestations.

Chronic cardiopathy

Chronic cardiac Chagas disease may present insidiously as congestive heart failure or abruptly with arrhythmias and/or thromboembolic events. Dilated congestive cardiomyopathy is an important manifestation of chronic Chagas disease that typically occurs years or even decades after acute infection. Apical aneurysm of the left ventricle is one of the hallmarks of this disease. Chronic chagasic heart disease is associated with myonecrosis and myocytolysis. Contraction-band necrosis occurs after transient hypoperfusion followed by reperfusion, as occurs with local spasm of the coronary microvasculature. Focal and diffuse areas of myocellular hypertrophy are observed with or without inflammatory infiltrates (Fig. 6), and fibrosis replacing previously damaged myocardial tissue is evident. The destruction of conduction tissue results in atrioventricular and intraventricular conduction abnormalities. In areas where the disease is endemic, the presence of right-bundle branch block (RBBB), associated with an anterior fascicular block, is highly suggestive of chagasic cardiopathy. Conduction defects may necessitate the placement of a pacemaker.

Chronic gastrointestinal manifestations

Chagas disease is associated with the loss of neurons of the myenteric plexus. Lesions of the autonomic nervous system produce functional disorders in hollow visceral muscular organs. Initial damage to the nervous system occurs during acute *T. cruzi* infection and may be the consequence of the increase in local inflammatory mediators. Further neuronal loss occurs slowly during the chronic phase of the infection. The development of clinically-manifest chronic gastrointestinal disease may take several decades, and the determinants of this progression are unknown.

The colon is frequently affected in chronic Chagas disease. Although the entire colon may be enlarged, dilatation is often confined to the sigmoid colon. Constipation is a common complaint. Symptomatic patients may have disorders of motility that antedate by years the radiological diagnosis of megacolon. In patients with chagasic megacolon, there is a reduction in the number of ganglia throughout the colon. The esophagus is also frequently affected in patients with long-standing *T. cruzi* infection. Patients with megaesophagus may have <5% of the normal number of ganglia and this loss of neurons is uniform along the length of the organ, including the grossly normal abdominal portion of the esophagus. Typical symptoms of megaesophagus include dysphagia, odynophagia, chest pain, cough, and regurgitation. Mega-gall bladder and mega-ureter also have been reported in patients with chronic *T. cruzi* infections.

Other Clinical Syndromes

Transfusion-associated *T. cruzi* infection

The transmission of *T. cruzi* by transfusion of blood donated by asymptomatic persons who harbor the parasite historically has been a major public health problem in the countries in which Chagas disease is endemic. This mode of transmission of *T. cruzi* has been essentially eliminated in most of the endemic nations as mandatory programs for screening donated blood have been implemented. As noted above, several transfusion-associated instances of *T. cruzi* transmission have been reported in the United

Fig. 6 Endomyocardial biopsy from a patient with chronic Chagas' disease. Note the inflammation and fibrosis. Courtesy of Dr. Alain C. Borczuk, North Shore University Hospital, Manhasset, NY.

States as a consequence of the immigration of infected persons, and widespread screening of donated blood began here in early 2007.

Immunosuppression and transplantation

The incidence of reactivation of *T. cruzi* infection in immunosuppressed people is not known. In view of the possibility of acute reactivation of *T. cruzi*, patients who are at risk of being infected and for whom immunosuppressive treatment is being planned, either as primary or posttransplantation therapy, should be tested serologically and, if positive, should be monitored closely while immunosuppressed for evidence of reactivation. Several dozen HIV-infected patients with reactivation of chronic *T. cruzi* infections have been described. Interestingly, many of these patients developed cerebral lesions radiographically similar to those observed in AIDS patients with cerebral toxoplasmosis. As with the latter, cerebral lesions do not occur in immunocompetent patients chronically infected with *T. cruzi*. Finally, more than a hundred patients with end-stage Chagas heart disease have undergone cardiac transplantation in Brazil, and the procedure has been performed in a couple of dozen *T. cruzi*-infected people in the United States. Because of the intense postoperative immunosuppression used in the early series of patients transplanted in Brazil, life-threatening reactivation of *T. cruzi* infection occurred in some of these patients. However, lower doses of immunosuppressive drugs have been used for many years now and reactivation of *T. cruzi* infection has become much less of a problem. The overall survival of chagasic patients receiving cardiac transplants is better than the total group of patients transplanted for other reasons.

Pathogenesis

Animal models have been used extensively to evaluate the pathogenesis of chagasic heart disease. For example, alterations in cardiac choline acetyltransferase, acetylcholine, norepinephrine, and β -adrenergic adenylate cyclase complex in association with chronic *T. cruzi* infection have been described in experimental animals. The expression of cytokines and NOS2 in the myocardium has been suggested as a possible cause of myocardial dysfunction. Morphological changes during acute *T. cruzi* infection may also be important in the pathogenesis of the myocardial lesions. For example, reduced numbers of autonomic ganglia are associated with clinically-manifest cardiac as well as gastrointestinal Chagas disease, and as noted this may be a direct result of destructive processes that are part of the early phase of the illness. The immunology of *T. cruzi* infection has been studied extensively in animal models and in humans, and a large portion of these efforts have focused on a possible role for autoimmunity in the pathogenesis of chagasic lesions. There is evidence from studies in mice that both humoral and cell-mediated components of the immune system are important in host resistance, as is genetic background. CD8⁺ T cells are important in the pathogenesis of *T. cruzi* infection. The possible roles of cytokines in the pathogenesis of *T. cruzi* infections also have been the subject of intense investigation. Cytokines are elevated during acute murine infection and may contribute to the pathogenesis of the disease. Increased levels of IL-1 β , TNF- α , and IL-6, expressed in infected endothelial cells, result in leukocyte recruitment, coagulation, and smooth muscle cell proliferation. The role of cytokines and nitric oxide in the killing of the parasite has received considerable attention as well. Nitric oxide, IFN- γ , TNF- α , and IL-12 all appear to be involved in intracellular killing. The 21-amino acid peptide endothelin-1 and the eicosanoid thromboxane A₂ have also been implicated in the pathogenesis of *T. cruzi* infection. Trypanosomes contain proteases, gelatinases, and collagenases capable of degrading native type I collagen, heat-denatured type I collagen (gelatin), and native type IV collagen. Proteolytic activities against laminin and fibronectin are also present. These enzymes may play important roles in the degradation of extracellular matrix and the subsequent tissue invasion by *T. cruzi*. It has been proposed that the degradation of the collagen matrix, evident in acute murine Chagas disease, may result in chronic pathology such as apical thinning of the left ventricle. *T. cruzi* uses adipose and intestinal tissues as reservoirs and results in persistent infection of heart or other organs.

Diagnosis

The diagnosis of acute *T. cruzi* infection is generally made by the detection of parasites. Active trypomastigotes frequently can be seen by microscopic examination of fresh anticoagulated blood or buffy coat, and organisms can often be seen in Giemsa stained thin and thick blood smears as well. If the organisms cannot be detected by these approaches, one may inoculate blood specimens or buffy coat into specialized liquid medium or intraperitoneally into mice. The disadvantages of these approaches are their lack of sensitivity and the fact that the parasites are usually not seen in positive cultures or infected mice for several weeks. Assays based on the polymerase chain reaction (PCR) have been described, and the results obtained suggest that this approach may be the most sensitive method for detecting acute *T. cruzi* infections. When acute Chagas disease is suspected in an immunocompromised patient and these methods fail to demonstrate the presence of parasites, additional tissue specimens should be examined. These patients can pose a difficult diagnostic problem because they may present with fulminant clinical disease and low parasitemias that cannot be readily detected. Surprisingly, parasites can sometimes be seen in atypical sites, such as pericardial fluid, bone marrow, brain, skin, and lymph nodes, and thus, these tissues also should be investigated when indicated.

The diagnosis of chronic Chagas disease is generally based on detecting specific antibodies that bind to *T. cruzi* antigens. Several dozen serological assays based on a variety of technologies are used in Latin America for detecting antibodies, such as the indirect immunofluorescence test and the enzyme-linked immunosorbent assay (ELISA). These and other conventional serologic assays are used widely for clinical diagnosis and screening donated blood, as well as in epidemiological studies. False negative and false positive reactions, however, have been a persistent problem with many of these assays. At the present time only two tests available in the United States are approved by the FDA for clinical testing. The first is a lysate-based ELISA (Hemagen Chagas Kit; Hemagen Diagnostics, Inc., Columbia, MD), and the other is an ELISA based on recombinant antigens (Chagatest Elisa Recombinante; Laboratorios Wiener, Rosario, Argentina). Screening of the US blood supply currently is being done with a lysate-based ELISA

(Ortho *T. cruzi* ELISA Test System; Ortho-Clinical Diagnostics, Raritan, NJ), but this test has not been cleared for clinical use. An automated blood screening assay based on four chimeric recombinant antigens is being developed (PRISM Chagas Assay; Abbott Laboratories, Abbott Park, IL) and a test based on a blot format is being developed with the same antigens for confirmatory testing (Abbott Chagas Immunoblot Assay). An immunoprecipitation assay based on iodinated *T. cruzi* proteins (RIPA) has been shown to be highly specific as well as sensitive when used in clinically and geographically diverse groups of infected people. The RIPA currently is being used as the confirmatory assay to test all donor samples that are positive in the Ortho screening assay, and it is also available for clinical testing.

The detection of chronic infection by testing for parasite antigens in blood and urine has been studied, but this approach has not achieved results comparable to those obtained by serologic methods. PCR-based assays for detecting chronic *T. cruzi* infections have been studied extensively, but their usefulness has not been established definitively. It would appear that this approach would be particularly suited for the task of detecting the low number of parasites circulating in the blood of chronically infected patients, but sampling issues and the possibility that parasitemias may in fact be intermittent and thus limit the sensitivity of the assays. Moreover, false positive results have been an issue in some laboratories. The most likely niche for PCR-based assays is in diagnosing congenital *T. cruzi* infections in the days and weeks after birth when serological tests are made useless by the presence of maternal anti-*T. cruzi* antibodies.

An analytical study, using the case-control design, which included 205 people, was performed in Colombia. The comparative analysis among the different methods suggests that the diagnostic strategy of *T. cruzi* infection in patients with chronic Chagas disease can be performed using ELISA assays based on recombinant proteins and/or synthetic peptides, which show higher diagnosis performance and can confirm and exclude the diagnosis of *T. cruzi* infection. The molecular methods show poor performance when used in the diagnosis of patients with chronic Chagas disease.

Treatment

The treatment of *T. cruzi* is unsatisfactory. Nifurtimox (Lampit, Bayer 2502) and benznidazole (Rochagan, Roche 7-1051), the two drugs available for treating this infection, lack efficacy, must be taken for extended periods, and may cause severe side effects. Both drugs reduce the severity of acute Chagas disease, and it is thought that about 70% of acute patients treated with a full course of either nifurtimox or benznidazole are cured parasitologically. This cure rate decreases as a function of the time patients have been infected and may be < 10% in persons who have harbored the parasite for many years. There are no convincing data from properly controlled trials that treatment with either nifurtimox or benznidazole is beneficial in persons with long-standing infections. Chagas experts in both Brazil and Argentina currently recommend specific treatment only for patients with acute and congenital *T. cruzi* infections, and for chronically infected children. Therapy for adults assumed to have long-standing infections is not recommended, regardless of clinical status. In 2015, a prospective, multicenter, randomized study was completed. Trypanocidal therapy with benznidazole in patients with established Chagasic cardiomyopathy significantly reduced serum parasite detection but did not significantly reduce cardiac clinical deterioration through 5 years of follow-up (the BENEFIT Multicentric Trial).

Allopurinol and several antifungal azoles have been shown to have some anti-*T. cruzi* activity in in vitro experiments and in animal studies, but none has a level of activity that would warrant its use in place of nifurtimox or benznidazole.

Surgery is often necessary for gastrointestinal megasyndromes. As noted, persons with severe Chagas heart disease may benefit from heart transplantation. Stem cell transplantation currently is being evaluated in patients with severe heart failure due to *T. cruzi* infection.

Prevention

No vaccine or chemoprophylactic drug is available for preventing the transmission of *T. cruzi* in any context. The elimination of domiciliary vectors by spraying residual insecticides, improving housing conditions, and educating populations at risk are the linchpins of the widely successful programs for elimination of *T. cruzi* transmission to humans in the endemic countries. Serologic screening of blood donors is practiced throughout most of the endemic range and as a consequence transmission of *T. cruzi* by transfusion has largely been eliminated. The risk faced by short-term travelers to endemic regions of acquiring *T. cruzi* infection is extremely low, as only three such instances have been reported. Nonetheless, persons traveling to rural areas in endemic countries should avoid sleeping in primitive dwellings and should use insect repellent. Laboratorians who work with parasites or infected vectors should use appropriate protective equipment.

Trypanosoma brucei

Human African trypanosomiasis, or “sleeping sickness,” is caused by two subspecies of hemoflagellate protozoa; *Trypanosoma brucei gambiense*, and *T. brucei rhodesiense*. The former causes the West African or gambiense form and the latter, the East African or rhodesiense form. Although these subspecies cause similar diseases, the West African form usually evolves over months to years and ends fatally if it is not treated. The East African form usually kills its host in weeks to months. These diseases exist in Africa wherever the various species of tsetse flies belonging to the genus *Glossina* are found.

Organism and Life Cycle

Trypanosoma brucei gambiense and *T. brucei rhodesiense* are pleomorphic flagellates 15–30 μ in length by 1.5–3.5 μ in breadth. The two subspecies are morphologically indistinguishable. There are two forms of trypomastigotes that circulate in the bloodstream, long

slender organisms that are capable of dividing, and short stumpy forms that are thought to be nondividing parasites that are infective for tsetse flies. There are no intracellular forms. At various stages of the disease, trypomastigotes may be found in peripheral blood, lymphatics, lymph nodes, cerebrospinal fluid, and neural tissue (Fig. 7). Other than humans, there is no important reservoir host for *T. brucei gambiense*, whereas *T. b. rhodesiense* is primarily a parasite of wild game animals. In the tsetse fly, trypomastigote forms ingested with a blood meal settle in the posterior midgut, where they multiply by binary fission for approximately 7–10 days and then migrate anteriorly to the foregut, where they remain for 2–3 weeks. Finally, they enter the salivary glands, continue to replicate, and after several cycles of division, transform into infective metacyclic trypomastigote forms. These organisms are inoculated the next time a mammalian host is bitten, and once in a human host, trypomastigotes multiply by binary fission in the blood, lymph, and other extracellular spaces. The central nervous system (CNS) eventually is invaded and multiplication continues there as well.

The haploid genome size of *T. brucei* spp. is approximately 35 Mb, although there is up to 14% variation in isolates of the same subspecies and up to 29% between the two subspecies. There is a minimum of seven resolvable chromosome pairs on pulse-field gel electrophoresis in the size range of 1.1–6 Mb. Homologous chromosomes, when probed in Southern blots, can differ in size by up to 20%. In addition to the large chromosome pairs, *T. brucei* contains approximately 100 linear minichromosomes ranging in size from 50 to 150 kb. Minichromosomes contain tandem arrays of 177-bp repeats as well as transcriptionally silent copies of variant surface glycoprotein (VSG) genes proximal to their telomeres. *T. brucei* contains approximately 1000 genes capable of coding for VSG genes, which are switched at a rate of 102–106 switches per generation. This process serves as the main mechanism of immune evasion for *T. brucei*. Only one VSG expression site (ES) is active at any given time. There are 15–20 ESs per genome, all at subtelomeric locations. In addition to the VSG genes, several upstream genes, called expression site-associated genes (ESAGs), are also transcribed. Three types of DNA rearrangements are associated with ES switching—duplicative transposition, telomere exchange, and telomere conversion. Transposition involves the 1.6-kb VSG, in addition to a 1.5-kb proximal sequence. Thus, a minimum of 8% of the genome is devoted to VSG coding and flanking sequences. As mentioned previously, a large fraction of the 25% of the genome found in the minichromosomes also contributes to VSG diversity. The modified DNA base “J” (β -D glucosyl-hydroxymethyluracil), unique to organisms in the order Trypanosomatidae, replaces up to 1% of thymidines, and its frequency is higher in repetitive DNA adjacent to transcriptionally silent telomeres, including the (GGGTTA)_n telomeric hexamer.

T. brucei genes are transcribed as large polycistronic units that then undergo *trans*-splicing so that all mature mRNAs contain the same 39-nt sliced leader at their 5' ends. In contrast, with the exception of an 11-nt intron in a tRNA^{Tyr}, *T. brucei* genes contain no introns and, hence, do not undergo *cis* splicing. The spliced leader is also notable for the presence of a 7-methyl-guanosine 5' cap, a promoter-like region consisting of four methylated nucleotides at the 5' end, similar to that found upstream from ES regions and from genes that encode procyclic stage-specific coat protein (procyclic acid-rich protein (PARP), also called procyclin). Transcription from the PARP and VSG promoters, similar to that from the trypanosome rRNA promoter, is α -amanitin-resistant, suggesting transcription by RNA Polymerase I. Stage-specific gene expression is also influenced by 3' untranslated portions of mRNAs, mediated through changes in mRNA stability and in efficiency of mRNA maturation. The sequence influencing stage specificity of VSG mRNA abundance is localized to a region 97 nt upstream from the polyadenylation site. Retroposon-like elements are also scattered throughout the genomes of these parasites. The best studied is a 5-kb sequence, designated *ingi* (Swahili for many), that is similar to reverse transcriptase genes in other organisms. There are approximately 400 copies of *ingi*, making up to 5% of the *T. brucei* genome.

Another interesting feature of trypanosome genetics, which is shared with other members of the order Kinetoplastida, is the phenomenon known as RNA editing. The kinetoplast DNA is organized as an interlocking and supercoiled network of approximately 50 maxicircle DNA molecules (20- to 30-kb) and many thousands of minicircle DNA molecules (1.0 kb in *T. brucei* and 1.6 kb in *T. cruzi*). The maxicircle DNAs encode about a dozen mitochondrial proteins. The maxicircles and minicircles both encode small (50–100 bp) guide RNAs that serve as templates for the insertion, and less frequently deletion, of uridines in the primary RNA transcripts of the maxicircle mitochondrial genes. In some cases, nearly 50% of the mature mRNAs consist of uracils inserted

Fig. 7 Trypomastigote of *Trypanosoma brucei gambiense* in the bloodstream. Courtesy of the American Society of Tropical Medicine and Hygiene/Zaiman “A Presentation of Pictorial Parasites.”

posttranscriptionally by the editing process. Studies comparing homologous nuclear genes between *T. brucei* and *T. cruzi* have demonstrated a large evolutionary divergence in codon use. A comparison of the nuclear small and large subunit rRNA gene sequences yields genetic distances comparable to those between plants and animals.

Epidemiology

Sleeping sickness (*Trypanosoma brucei gambiense* and *T. b. rhodesiense*) and veterinary trypanosomiasis caused by *Trypanosoma brucei* subgroup parasites continue to be responsible for much human suffering and economic loss (see Table 1). These agents are endemic and enzootic in an area of sub-Saharan Africa covering 10 million square kilometers. Approximately 50 million people are at risk for becoming infected with these parasites and tens of thousands of new cases of human African trypanosomiasis occur each year. Exact numbers are not available because the acquisition of reliable health statistics is difficult in the developing countries where sleeping sickness is endemic. Human African trypanosomiasis has undergone resurgence, and in recent years major epidemics have occurred in the Central African Republic, Ivory Coast, Chad, Sudan, and several other endemic countries. Losses of cattle due to trypanosomiasis have had an enormous economic impact in many regions. Human African trypanosomiasis is restricted to those areas south of the Sahara in which the annual rainfall exceeds 500 mm (i.e., 20 in.) because the larval stages of the tsetse fly are vulnerable to desiccation. Thus, the gambiense form occurs in the western portion of tropical Africa and focal incursions eastward all the way over to Lake Victoria and into southern Sudan. The rhodesiense form is found in the southeastern portion of Africa, north of South Africa. There is some overlap in the endemic ranges of these two forms of the disease. Humans are the only important reservoir of *T. b. gambiense*. The cycle of gambiense disease is maintained only where there is a close relationship between humans and tsetse flies that belong to the *G. palpalis* group and preferentially feed on human blood. In contrast to gambiense disease, the cycle of *T. brucei rhodesiense* is maintained in wild mammals, and humans are only incidental hosts. The vectors of *T. b. rhodesiense*, which belong to the *G. morsitans* group, inhabit the relatively dry eastern African savannas and preferentially feed on wild ungulates that are relatively trypanotolerant and maintain infective parasitemias for long periods. Nonetheless, there have been instances in which East African Trypanosomiasis has reached epidemic proportions. Human cases of rhodesiense trypanosomiasis typically occur in young adult men who have occupations in which they are exposed to tsetse flies. In epidemics, however, all age groups are infected, and mechanical transmission is thought to occur in this context. Tourists from nonendemic areas may acquire this infection. This occurs via the blood-filled proboscis of a fly, which may be interrupted while taking a blood meal from an infected individual. When the fly bites an uninfected host within 2–3 h, the blood from the infected host becomes a parasite-bearing inoculum. In contrast to *T. cruzi*, congenital transmission of African trypanosomes is extremely rare. Laboratory-acquired transmission has been reported.

Pathology and Pathogenesis

Metacyclic infective trypomastigote forms are inoculated into the skin by the tsetse fly and multiply there. A characteristic hard and sometimes painful chancre is formed. By about day 10, long slender forms are found in the bloodstream and lymphatics, and for the

Table 1 African animal trypanosomiasis

Parasite	Host	Occurrence
<i>Trypanosoma vivax</i>	Cattle	Common, mild
	Equines	Rare, mild
	Sheep and goats	Rare, severe
	Camels	Rare mild
	Dogs	Not reported
	Pigs	Not reported
<i>Trypanosoma brucei brucei</i>	Cattle	Common, but most cattle tolerate well
	Equines	Common, severe
	Sheep and goats	Rare
	Camels common	Severe
	Dogs common	Severe
	Pigs	Not reported
<i>Trypanosoma congolense</i>	Cattle	Common, severe
	Equines	Rare, mild disease
	Sheep and goats	Rare
	Camels	Not reported
	Dogs	Not reported
	Cattle	Mild disease
<i>Trypanosoma evansi</i>	Equines	Common, severe
	Sheep and goats	Not reported
	Camels	Common, severe

Animal trypanosomiasis is of great economic importance in Africa and is associated with fever, anemia, thrombocytopenia, wasting, and death. These manifestations are mediated, in part, by cytokines.

next several days their numbers increase exponentially. Soon thereafter, the organisms nearly disappear from the bloodstream, only to reappear later. The interval between waves of parasitemia may vary from 1 to 2 weeks, with clinical symptoms accompanying each bout of parasitemia. Each successive wave of organisms represents a new crop of parasites expressing a VSG not previously expressed in that host, and it is through this process of sequential antigenic variation that the parasites stay one step ahead of the host's specific antibody responses. In response to infection, a marked early humoral antibody response, consisting predominantly of IgM, is seen regularly. These macroglobulins consist not only of antitrypanosomal antibodies directed against parasite surface antigens, but also include a variety of other antibodies such as heterophile and rheumatoid factor. As a result of polyclonal B cell activation, there also are many antibodies produced to a wide variety of antigens, including brain-specific auto-antibodies. In addition, antibodies directed against myelin basic protein, gangliosides, and cerebroside have been found in experimental models. Circulating immune complexes have been reported regularly and these may be responsible for the glomerulonephritis often accompanying acute and chronic disease. Cell mediated immunity also is important in this disease and nitric oxide may be important in the depression of T cell responsiveness and generalized immunosuppression.

Lymphadenopathy usually involves the posterior cervical, submaxillary, supraclavicular, and mesenteric lymph nodes. The advanced disease, often called stage II disease, involves the CNS. The microscopic examination of lymphatic tissues usually reveals generalized hyperplasia with diffuse proliferation of lymphocytes. Initially, affected lymph nodes are markedly hemorrhagic and contain a large number of trypomastigotes; later, the nodes may become small and fibrotic. A progressive, chronic leptomenigitis develops in stage II disease. The brain becomes edematous and there is prominent perivascular cuffing by glial cells, lymphocytes, and plasma cells. Morula cells, reactive astrocytes, and hyperplasia of microglial cells all have been described in brain specimens from patients with CNS disease, and demyelination occurs in chronic cases. Organisms can be found in the brain tissue near vessels and also may be present in the cerebrospinal fluid. There is a striking lymphocytosis in the cerebrospinal fluid and most of these lymphocytes are B cells. Glomerulonephritis, myocarditis, pericardial effusion, pulmonary edema, and hypoplastic bone marrow with an associated anemia may develop in some patients. The pathogenesis of the neuropsychiatric manifestations is poorly understood. Experimental models suggest that a variety of factors may be responsible (e.g., deposition of immune complexes and aberrant levels of brain neurotransmitters, prostaglandins, and cytokines).

Clinical Manifestations

Clinical manifestations of infection with *T. brucei gambiense* and *T. b. rhodesiense* are similar, except that the rhodesiense disease usually runs a much more fulminant course. Untreated patients with the latter typically die in weeks to months, whereas persons infected with *T. b. gambiense* may live for years and have long periods without symptoms. In both forms, the trypanosomal chancre may be evident several days after the bite of an infected tsetse fly. Within a week or two, the lesion becomes a large, red, painful nodule that may reach 5–10 cm in diameter. This nodule, which is reported to be more common in people of European descent, subsides spontaneously in a few weeks. In rhodesiense trypanosomiasis, the incubation period of the systemic disease typically is 2–3 weeks, whereas with the gambiense infection, the first symptoms may be noted many weeks or months after the acquisition of the infection. The early systemic disease is characterized by intermittent fevers, chills, headache, and generalized lymphadenopathy. In gambiense disease, the nodes in the posterior cervical triangle may become enlarged (i.e., Winterbottom sign) and, when present, strongly suggest the diagnosis in a patient with exposure to tsetse flies. Delayed deep hyperesthesia may occur over the tibia and moderate hepatosplenomegaly may be noted. Anemia and thrombocytopenia are frequent as well. Intermittent fevers may last for months to years with gambiense infection. In Europeans, a circinate erythematous rash or erythema multiforme is sometimes present. Untreated patients eventually develop signs of CNS invasion. Severe headaches, loss of nocturnal sleep, and a feeling of impending doom are typical. Following this, there may be progressive mental deterioration, with patients becoming incapable of caring for themselves. Tremors, especially of the tongue, hands, or feet, as well as generalized or focal convulsions may occur. Almost any neurologic and psychiatric manifestation can be seen with progressive mental deterioration until patients finally lapse into coma and die of intercurrent infections.

Diagnosis

A definitive diagnosis of African trypanosomiasis is made by detecting trypanosomes, and this can be done by looking for parasites in fresh and stained specimens of blood, bone marrow, lymph node aspirates, or, in late disease, the cerebrospinal fluid. If parasites are not seen in these specimens obtained from a patient whose history and clinical findings suggest African trypanosomiasis, efforts should be made to concentrate the organisms in blood. This can be done most simply by using commercially available quantitative buffy-coat analysis tubes. The parasites are separated from the blood components by centrifugation in these acridine orange-coated tubes, and are easily seen under light microscopy because of the stain. Alternatively, buffy coat obtained by centrifugation of 10–15 mL of anticoagulated blood can be examined microscopically as a wet preparation and after Giemsa-staining. All of these specimens also can be inoculated into specialized liquid-culture medium. Finally, a highly sensitive method for detecting *T. b. rhodesiense* is the inoculation of small volumes of specimens obtained from the patient into rodents. Patent parasitemias usually develop within a week or two in animals injected with specimens from people infected with *T. b. rhodesiense*. Unfortunately, host specificity precludes the use of this approach for diagnosing *T. b. gambiense*.

Several serologic assays are available to aid in the diagnosis of sleeping sickness, but the variable accuracy of these tests mandate that treatment decisions still be based on detection of the parasite. These assays are useful, none the less, in epidemiologic surveys.

Simple direct agglutination tests for trypanosomes performed on cards (CATT and TrypTect CIATT) are available commercially. A role for PCR-based assays for detecting African trypanosomes has not been defined. In advanced untreated sleeping sickness, the IgM level in the cerebrospinal fluid often is elevated, but it has no relationship to the presence of trypanosomes in the cerebrospinal fluid. After successful treatment, the IgM level declines gradually, disappearing after approximately 1 year and, thus, a persistently elevated level or an abrupt rise in the IgM months after treatment may indicate a relapse. IgM levels, however, should not be used as the sole method of diagnosis or prognosis.

Treatment

The chemotherapy of these diseases, both human and veterinary, has lagged remarkably behind that of other tropical diseases. The main chemotherapeutic agents for human trypanosomiasis remain pentamidine and suramin for the early-stage disease, and melarsoprol (Mel B, Arsobal) for the late-stage (CNS) disease. Difluoromethylornithine (DFMO, Ornidyl) is the only new useful addition to this list since the early 1950s. With the exception of suramin, resistance to the established agents is growing, and the toxicity of these drugs continues to be a problem.

Pentamidine is a water-soluble aromatic diamidine that has been in use since the 1930s. It is effective against early-stage *T. b. gambiense* infection, but is less effective against *T. b. rhodesiense* infection, and is ineffective against late-stage disease. African trypanosomes have a nucleoside transporter (adenine/adenosine: P2) that takes up pentamidine, resulting in the concentration of the agent at levels many times that in plasma. Many studies have focused on the mechanism of pentamidine action; however, none appears to have conclusively defined the target. It is known to bind to the minor groove of kinetoplast (i.e., mitochondrial) DNA, and to promote the cleavage of kinetoplast minicircle DNA, eventually leading to the development of dyskinetoplastic cells. Despite its effects on kinetoplast DNA, pentamidine has no effect on nuclear DNA, and dyskinetoplastic forms can persist in the bloodstream of mammals. Pentamidine also has been found to be a reversible inhibitor of S-adenosylmethionine (AdoMet) decarboxylase, an enzyme in the polyamine biosynthetic pathway. Although K_i values were in the 200 mM range, we now know that this internal concentration is achievable via uptake through the P2 nucleoside–pentamidine transporter. Other targets studied previously in trypanosomes include the inhibition of glycolysis and lipid metabolism, as well as the effects on amino acid transport and ion exchange. The facts that pentamidine does not kill trypanosomes outright and bloodstream forms persist after treatment argue for a sustained effect more consistent with interference with the nucleic acid metabolism.

Diminazene aceturate (Berenil) is an aromatic diamidine developed as treatment for bovine trypanosomiasis; however, its apparent low incidence of adverse reactions and significant therapeutic activity has led some physicians in endemic countries to use it extensively. It is effective against early-stage *T. b. gambiense* and *T. b. rhodesiense*. Diminazene has also been used in combination with melarsoprol for late-stage disease. Mechanistically, like pentamidine, diminazene has also been linked to kinetoplast DNA binding at the minor groove and cleavage of minicircle DNA. Similar to pentamidine, diminazene may also interfere with RNA editing and *trans*-splicing. Diminazene is also a more effective and noncompetitive inhibitor of AdoMet decarboxylase in trypanosomes, resulting in the reduction of spermidine content and elevating putrescine in the parasite. As with pentamidine, diminazene uptake occurs via the P2 nucleoside transporter, which allows significant accumulation from the external environment. Although diminazene has been used for many years on thousands of sleeping sickness patients, there is little published on its toxicity. This may in part be due to physicians who are unwilling to document human studies with an agent licensed for veterinary use. However, personal accounts of those using diminazene in humans indicate it is well tolerated.

Suramin is a sulfonated naphthylamine, which has been used successfully against early-stage sleeping sickness caused chiefly by *T. b. rhodesiense*. It was first used in 1922, developed from the closely related azo dyes, trypan red and trypan blue. Suramin has an extremely long half-life in humans, 44–54 days, as the result of avid binding to serum proteins. Suramin binds to many plasma proteins including LDL, which trypanosomes avidly bind and endocytose as a result of specific membrane receptors. LDL is a prime source of sterols for bloodstream trypanosomes. The uptake of suramin as a protein complex results in an internal concentration of 100 mM. Suramin has been shown to inhibit all of the glycolytic enzymes in *T. b. brucei* in the range of 10–100 mM, which in most cases is several-fold lower than for the corresponding mammalian enzyme. This specificity for trypanosomal enzymes was attributed to higher (i.e., more basic) isoelectric points for the parasite enzyme than the mammalian enzymes, allowing the negatively charged suramin to bind preferentially to the parasite enzymes. In practice, because most trypanosome glycolytic enzymes are contained in a membrane-bound cytosolic organelle, the glycosome, it is not likely that rapid massive binding occurs. This would rapidly induce lysis in bloodstream forms that depend on glycolysis as the sole energy-generating source. Rather, animals that are heavily infected with trypanosomes and given suramin show a slow decrease in parasite numbers, indicating that enzyme inhibition occurs slowly. Suramin may be affecting newly synthesized enzyme molecules in the cytosol before they are imported into the glycosome. Beyond the inhibition of glycolytic enzymes, suramin has also been found to affect thymidine kinase and dihydrofolate reductase. It is likely that suramin's action may be attributable to the inhibition of several of these enzymes.

Melarsoprol (Mel B, Arsobal) is an arsenical resulting from the efforts of Ernst Freidheim in the late 1940s. His initial compound, melarsen oxide, *p*-(4,6-diamino-*s*-triazinyl-2- γ l) aminophenylarsenoxide was complexed with dimercaptopropanol (British Anti-Lewisite) to form a less-toxic complex, melarsoprol. Until 1990, this was the only agent available for curing the late-stage (CNS) disease in both of East African and West African infections. It is usually given as two to four series of three daily injections. It is insoluble in water and must be dissolved in propylene glycol, and it must be given intravenously. Toxicity is an important concern with melarsoprol. This takes the form of reactive arsenical-induced encephalopathy, which is often followed by pulmonary edema and death in more than half the cases within 48 h. Although the mechanism of melarsoprol action has been extensively studied, it still

remains unclear. Parasites exposed to low levels (1–10 mM) rapidly lyse. Because the bloodstream forms are intensely glycolytic, any interruption of glycolysis should produce this effect. Thus a series of reports has detailed melarsoprol inhibition of trypanosome pyruvate kinase (ki, 100 mM), phosphofructokinase (ki, <1 mM), and fructose-2,6-bisphosphate (ki, 2 mM). It is likely that the rapid inhibition of fructose 2,6-bis-phosphate production is a key factor in halting glycolysis through down-regulation of pyruvate kinase. Other studies indicated that melarsoprol and melarsen oxide formed adducts with trypanothione (N1,N8-bisglutathionyl spermidine), a metabolite unique to trypanosomes and believed to be responsible for the redox balance of the cell and detoxification of peroxides. The melarsen-trypanothione adduct (Mel T) inhibits trypanothione reductase, which has been attributed to the mode of action. However, melarsoprol and related arsenicals may also bind to other sulfhydryl-containing agents in the cell, including dihydrolipoate and the closely adjacent cysteine residues of many proteins. Similar to pentamidine and diminazene, melarsoprol uptake into African trypanosomes has been attributed to entry through the P2 purine nucleoside transporter; thus, significant levels can be concentrated in the cell from a low external (plasma) concentration. Although most laboratory-generated melarsoprol-resistant strains have lost or modified the P2 transporter, clinical isolates appear to have retained uptake capacity.

Eflornithine DFMO (DL-*a*-difluoromethylornithine, Ornidyl) is the most recently developed agent for late-stage *T. b. gambiense* sleeping sickness. After initial testing in model infections, DFMO was studied extensively in human trials. The standard treatment regimen resulting from the trials indicate DFMO is >95% active when given intravenously. DFMO cured children, adults, and patients with melarsoprol-refractory strains, and patients with late-stage disease. The short plasma half-life of DFMO necessitates constant dosing when given as an i.v. drip. The most frequent toxic reaction was reversible bone marrow suppression, which was alleviated upon reduction of the doses. The major drawbacks with respect to DFMO are its cost, the duration of treatment, and its availability. DFMO rapidly and irreversibly binds to the catalytic site [cysteine 360 in mouse ornithine decarboxylase (ODC)], inactivating it. In culture, it blocks division of bloodstream trypanosomes, but it is not trypanocidal. In laboratory infections, DFMO cures when administered continuously in the drinking water as a 2% solution. Within 48 h of administration, DFMO reduces putrescine levels to zero, and reduces spermidine levels by ~75%. Trypanothione levels are also significantly reduced. As noted, DFMO is not trypanocidal and depends on a functional immune system to rid the host of nondividing forms. Morphologically, trypanosomes with multiple kintoplasts and nuclei are common, as are forms resembling “stumpy” blood forms. DFMO is curative for laboratory infections of *T. b. brucei* and *T. b. gambiense*, but not to all strains of *T. b. rhodesiense*. The reason for this selectivity is not known, although it is not due to uptake of DFMO, because it enters by passive diffusion, not transport. Levels of AdoMet are highly elevated in susceptible strains, but less so in refractory isolates. The elevated levels of AdoMet are due to an AdoMet synthase insensitive to its product. DFMO treatment leads to intracellular concentrations of ~5 mM, an increase of ~50-fold over untreated parasites. Trypanosome ODC is missing the PEST sequence in both procyclic and bloodstream trypanosomes, and this appears to be the major reason for the stability of the trypanosome enzyme. The remainder of the ODC molecule has >60% sequence identity with the mammalian enzyme, including a cysteine 360 residue at the demonstrated DFMO-binding site for the mammalian enzyme. Beyond this, trypanosomes lack a polyamine oxidase, which in mammalian cells converts spermine to the biologically active spermidine. Trypanosomes are also limited in their ability to transport putrescine and spermidine. This treatment has forced retirement of melarsoprol-based therapy for *T. gambiense* infections, and points to the need for development of an all oral therapy with a minimal dose regimen. New therapy must avoid the toxicity of melarsoprol, penetrate the blood brain barrier and be orally administered.

The usefulness of nifurtimox in combination with DFMO or melarsoprol as treatment for human African trypanosomiasis has been assessed in several recent trials especially with the emergence of resistance to DFMO. Outcomes obtained to date suggest that the addition of nifurtimox to adjusted doses of either of these two drugs results in increased efficacy, while reducing overall toxicity. Clinical studies with DFMO and Nifurtimox led to the development of combination therapy (Nifurtimox-Eflornithine Combination Therapy, NECT) which has become the new standard clinical regimen: Eflornithine 400 mg/kg, i.v. every 12 h per day for 1 week + nifurtimox 15 mg/kg every 8 h for 10 days. This regimen is 96% curative, has very little adverse reaction and reduces the eflornithine dosage from 4/day for 2 weeks to 2/day for 1 week (Priotto et al., 2009). Although this regimen is effective it still has drawbacks because it requires I.V. dosing and a total of 1 week of drug administration.

Recent studies have identified a series of boron-containing benzoxaboroles as having significant antitrypanosomal activity in vivo animal studies (Fig. 1; Fig. 27.5 in Bacchi et al., 2013). These compounds are orally available and are curative vs. early stage and CNS laboratory model infections (Nare et al., 2010; Jacobs et al., 2011). A series of these benzoxaboroles were initially screened in a high throughput in vitro assay at Scynexis, Inc. Initially, two classes of compounds, AN2920 (6-sulfides) and AN3520 (6-carbamides), were deemed interesting and proceeded to further optimization by Anacor Pharmaceuticals, Scynexis Inc. and Haskins Laboratory of Pace University through a grant from Drugs for Neglected Diseases initiative (DNDi) (Bacchi et al., 2013). These compounds and close analogs were then tested in a range of in vitro ADME (absorption, distribution metabolism and elimination) before undergoing in vivo testing in mice. The animal testing revealed that of approximately 146 compounds tested in an early stage HAT model, 25 were curative. Of these, 12 were also curative in a CNS model (C.J. Bacchi, unpublished) when administered orally, b.i.d. or QD × 4 days at 50 mg/kg. Further study of these analogs included pharmacokinetic testing showing rate of removal from the bloodstream, metabolic stability in the blood, and ability to cure at low dosing. Two analogs, SCYX6759 and SCYX7158, were superior to the other analogs. The differences in structure being a fluorine atom added to the 4 position of the benzamide of AN3520 to yield 6759. The structure was curative for a stage 2 HAT model at 50 mg/kg b.i.d. × 14 days. The 3,3-dimethyl analog added on the borol ring of 6-carboxamide (AN3520) yielded SCYX7158. This compound had impressive efficacy with the CNS model TREU667 curing 100% of mice at 25 mg/kg q.d. × 7 days and an 80% cure at 12.5 mg/kg q.d. (Nare et al., 2010; Jacobs et al., 2011).

Studies on the mechanism of action of SCYX7158 (Wall et al., 2018) using an over expression screening approach has identified cleavage and polyadenylation specificity factor 3 [CPSF3 nuclease] as a potential target of SCYX7158 and a mechanism by which treatment inhibits mRNA maturation. Molecular docking and CRISPR-Cas9-based editing have also demonstrated how SCYX7158 can block the active site and mRNA processing by the parasite, but not the host. Another oxaborole (AN3661) was also found to be active against *Plasmodium falciparum* and the target was CPSF3 (Sonoiki et al., 2017, in Wall et al., 2018). Other trypanosomatids besides *T. b. brucei* spp., such as *T. cruzi* and *Leishmania* spp. have CPSF3 catalytic site residues identical to the *T. b. brucei* sequence (Wall et al., 2018). Thus CPSF3 can now be considered as valid antitrypanosomal drug target and the oxaboroles and similarities in protozoan CPSF3 suggest both clinical and veterinary applications may be valid.

Currently SCYX7158 (acoziborole) is undergoing phase II and III clinical trials after successful phase I testing. In the phase II, III trials, 7158 is proving curative in late stage infections after a single 960 mg oral dose. The half-life is approximately 18 days in humans, which explains the single dose efficacy. There is no reported toxicity. Also interesting is the fact that SCYX7158 is curative in cattle with *T. b. brucei* and *T. congolense* disease (C. Mobray, personal communication).

Prophylaxis and Prevention

Trypanosomes cause complex public health and epizootic problems in many developing countries in Africa. Control programs concentrating on the eradication of vectors and drug treatment of infected people and animals have been in operation in some areas for decades. Considerable progress has been made in a number of regions, but the lack of agreement on the best approach to solving the problem of African trypanosomiasis, combined with a paucity of resources, stands in the way of effective control. Individuals can reduce their risk of becoming infected with trypanosomes by avoiding tsetse fly-infested areas, by wearing clothing that reduces the biting of the flies, and by using insect repellants. Chemoprophylaxis with suramin or pentamidine can be effective, but it is not clear which populations should use this as a preventive measure. No vaccine is available to prevent the transmission of the parasites.

Glossary

BLAST search An electronic comparison of a gene sequence with a database of sequences to determine the extent of similarity.

Cryoprotectant A material, such as bovine serum or skim milk, that protects cells from damage during freezing.

Culture In microbiology, the growth of an organism on agar or other nutrient medium.

GenBank A searchable database of gene sequences maintained by the National Center for Biotechnology Information (NCBI). A BLAST search of gene sequences can be conducted at this website.

L-drying A method to preserve microbial cultures that relies on drying unfrozen cells.

Lyophilization A method to preserve microbial cultures that relies on drying frozen cells.

Materials transfer agreement A legal document between parties that governs the transfer of research materials.

Patent culture A culture that is maintained in conjunction with a patent application.

Strain An isolate of a microbial species.

Defining Statement

Microbial culture collections, also known as Biological Resource Centers (BRC), are primary suppliers of microbial cultures (germplasm) for medical, agricultural, and biotechnological research and development. A major goal of culture collections is long-term preservation of strains without genetic change. Culture collections are also centers of taxonomic and microbiological expertise.

Microbial Culture Collections – Applications and History

Microbial culture collections, increasingly known as BRC, are primary suppliers of microbial cultures (germplasm) for medical, agricultural, and biotechnological research and development. Culture collections throughout the world have as their primary mission the preservation and distribution of germplasm that has been demonstrated to have significance to the microbiology community. The importance of a particular strain may be as a reference for medical, agricultural, biotechnological, or taxonomic research, use as an assay organism for testing or screening, or in relation to a parent application for a product or process in which it is

This article is an update of C.P. Kurtzman, D.P. Labeda, Type Culture Collections and Their Databases, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 306–312.

involved. Alternatively, the strain may be placed in a collection in regard to a publication in which it was cited as part of the investigation. The latter deposit is essential so that later investigators may repeat or advance published research, which would be impossible in the absence of the strains involved.

The major culture collections of the world also serve as centers of excellence for research on systematic and taxonomy, partly because the identification and characterization of strains is an integral function of collections and because the availability of a large collection of strains lends itself to this type of research. A major change in methodology for strain identification has been the development of molecular methods that are based on gene sequence comparisons. Much of the molecular work is done in culture collections or in collaboration with collection scientists. The product, species-specific gene sequences, or entire genome sequences, deposited in internationally accessible databases such as GenBank, has allowed even the nontaxonomist to sequence a specific microbial gene, conduct a BLAST search of deposited DNA sequences, and receive an accurate identification. Sequence analysis has also resulted in the recognition that microbial diversity is much greater than initially thought, and thus an enormous number of new microbial species may be available for exploitation in biotechnological and other applications. In this context, culture collection scientists often provide advice on strain and species selection for various aspects of research and development.

Culture collections trace their history to the early beginnings of microbiology, and the first culture collection established specifically to preserve and distribute strains to other researchers was that of Professor Franriek Kráí in Prague during the 1880s. Upon the death of Professor Kráí in 1911, this collection was acquired by Professor Ernst Pribham who transferred it to the University of Vienna and issued several catalogs listing the collection's holdings. Part of this collection was brought to Loyola University in Chicago by Pribham in the 1930s. Many of these strains were subsequently transferred to the American Type Culture Collection (ATCC) upon Pribham's death, but others remained in the collection at Loyola University. The Vienna portion of the Pribham Collection was apparently lost during World War II. The next oldest culture collection, the Centraalbureau voor Schimmelcultures (CBS), was founded in 1906 and is located in Utrecht, the Netherlands. At about the same time, a large number of filamentous fungi were isolated from spoiled agricultural products by Charles Thom at the US Department of Agriculture (USDA) in Washington, DC, and these well-authenticated cultures formed the nucleus for the fungal collections at both the ATCC and the Agricultural Research Service Culture Collection (NRRL). Both of these collections have served as repositories for main orphaned cultures collections that were previously established in individuals or institutions, such as the N. R. Smith Bacillus Collection or the US Army Quartermaster Collection. Consequently, culture collections receive strains from individual scientists as well as by accessioning other collections that may be abandoned for various reasons. Publicly funded collections have predominated in recent years because many of the large private pharmaceutical collections, with worldwide strain coverage, have either been abandoned or become inactive as emphasis in the pharmaceutical industry has shifted from antibiotic discovery to other types of products.

Types of Culture Collections

General Collections

Large culture collections were often initially established to maintain and provide type cultures and other reference strains, and hence use of the name Type Culture Collection. The type culture is the strain chosen to represent a new species when it is described. Even if other strains are known, it is the type culture that is the primary taxonomic representative of a species. Before strains were characterized from gene sequences, it was not unusual to find misidentified strains attributed to a particular species, and for this reason, gene sequences from type strains form the generic basis for species identification.

Most culture collections, even those that are large, are specialized in some manner. Certain collections might have a preponderance of fungi or bacteria while maintaining fewer species of other microorganisms (Table 1). Consequently, it may be necessary to request strains from several collections if a study requires a diversity of microorganisms. Protocols for obtaining cultures are discussed in a later section.

Patent Collections

With the discovery of microbiologically synthesized antibiotics in the 1940s, a large number of parents were tiled to protect these processes. Since then, many other microbiological processes have also been patented. To accommodate this new technology, the US Patent and Trademark Office implemented in 1949 a new requirement that cultures be deposited in conjunction with parent applications concerning microbiological inventions. The reasoning was that for chemical, electrical, or mechanical patents, a diagram or formula can sufficiently describe the invention, whereas in a microbiological patent, illustrations and narrative descriptions are generally inadequate to define sufficiently the microorganism used and therefore comply with the requirement for a full and complete disclosure of the invention. The Agricultural Research Service (ARS) Culture Collection was asked by the US Patent Office to assume the responsibility of accepting patent cultures, thereby becoming the first US culture collection, and apparently the first in the world, to accept patent cultures. The first culture was *Streptomyces aureofaciens* NRRL 2209, the strain deposited by the American Cyanamid Company of the United States for aureomycin production. Shortly thereafter, the ATCC, as well as several foreign collections, began to accept patent cultures as well.

Cultures may be deposited for US or foreign patent applications, but multicountry filings complicated the issue of patent culture deposits. The Patent Cooperation Treaty (PCT), which first became effective in 1970, and the European Patent Convention (EPC), which was implemented in 1977, allowed for filing a single parent application that included all member countries of the above

agreements. However, the issue of patent culture deposits in each country named in a multicountry patent application was not resolved until 1977 with the implementation of the Budapest Treaty on the International Recognition of the Deposit of Microorganisms for the Purposes of Patent Procedure, known simply as the Budapest Treaty. The importance of this treaty is that a single culture deposit satisfies the requirement for a deposit in all countries that are signatories of the Treaty, which includes most industrialized countries. Culture collections in most of these countries have now been certified as International Depositary Authorities under the Budapest Treaty. Cultures deposited under the Budapest Treaty must be maintained for 30 years and for 5 additional years after the last request. The special requirements for distributing patent cultures are discussed below.

Safe Deposit of Cultures

Oftentimes, a laboratory will have an important research culture but does not want to place it in the accessible holdings of a culture collection. In view of this, some culture collections offer a safe deposit option. The culture is not accessioned into the general part of the collection, but is maintained as a private deposit, for which the collection charges a fee.

Other Services

In addition to providing cultures, many culture collections offer related services, some of which require a fee. Among these services are advice on strain selection, advice and training on culture maintenance, microbial strain identification, taxonomy workshops, sale of biological reagents, custom preparation of inoculum for fermentation processes, various types of biological testing, and research and development work.

Databases and Other Informational Services

An essential requirement for all culture collections is the maintenance of records that provide an accession number for strains acquired along with the name of the strain, information regarding the source of the strain, such as where and from what substrate it was isolated, and if the strain has accession numbers in other collections (e.g., cross-referencing). In the early days of culture collections, this catalog might have been a handwritten notebook or card file full of note cards. The World Federation for Culture Collections (WFCC) recognized the importance of documenting strain information and made suggestions regarding the types of data that should be collected and cataloged in its Guidelines for the Operations of Collections of Microorganisms.

With the advent of computers that provided ready access, larger collections were quick to adopt them for management of data relevant to their holdings and as the size, cost, and complexity of computers diminished, virtually every collection of any size currently has catalogs of their holdings maintained electronically in some format. The increasingly stringent regulatory environment of the modern world has made it essential to maintain a growing amount of data on strains in collections. For instance, the Convention on Biodiversity requires collections to track the provenance (or history) of strains back to the original country of origin, even if the strain has come through many other laboratories during its path to the current collection. Concerns about biosecurity make it crucial that inventory and distribution information on microbes potentially dangerous to animals, humans, or crops be made readily available.

Publicly available catalogs are a requirement in the WFCC Guidelines of Culture Collections, and the advent of the Internet has made it possible for collections to provide online, searchable computer databases as their public access catalogs. These online collection databases can be typically searched for the name of a microorganism, an accession number in the catalog being searched, or for a number in other collections, and in some cases for properties of the strain, such as the ability to make a particular product, such as an enzyme or antibiotic, or for some specific activity, such as the production of yogurt or industrially important organic acids.

The central registry for collections throughout the world can be found at the WFCC website (<http://www.wfcc.info/>) and there are currently 525 culture collections in 67 different countries. At least 182 of the collections have active websites and many of these have online catalogs of their holdings. Recently, there have been several attempts to integrate the information regarding microbial strains held in many different collections through a Web-based portal at a single site. Examples include the Agent to Help Microbial Information Integration (AHMII) on the aforementioned website and the StrainInfo.net portal (<http://www.straininfo.ugent.be>) at the University of Ghent in Belgium.

Preservation of Cultures

A major role of culture collections is to maintain microbial strains for long periods in a genetically unaltered state. Serial transfer on agar or other media is time-consuming and often leads to genetic changes as the organism adapts to its new environment, the culture medium. For this reason, a number of long-term storage procedures have been developed that maintain strains in metabolically and genetically inactive states. Three of these procedures are described here.

Lyophilization

The procedure of lyophilization freeze-dries cultures to an inactive, low-moisture state. The process starts with suspending actively growing cultures in a cryoprotectant such as sterile bovine serum or skim milk. The volume of cryoprotectant needed depends on the size of the ampoule used. Ampoules used in the NRRL are made from 6 mm outside diameter Pyrex glass tubing, which is cut in lengths of 100 mm. One end is fire polished in a gas oxygen flame to remove sharp edges and the other end is sealed by flame. In the ARS process, ~0.1 ml of suspension containing cells and bovine serum is added aseptically to the sterile, labeled lyophil tubes, which have a small cotton plug. After filling, the cotton plug is pushed a short distance into the tube and the excess cotton is burned off in a gas flame. The tube is then inserted into a rubber connector on the manifold of the lyophil machine. After all the tubes are inserted, the manifold is lowered so that the ends of the tubes are immersed in a 50% ethylene glycol bath cooled to approximately -30°C with dry ice. Once the contents of the tubes are frozen, the bath temperature is raised to approximately -20 to -25°C with fresh ethylene glycol and the vacuum pump is started. Drying takes about 2 h and is finalized by raising the manifold and allowing further drying at room temperature. Each ampoule is sealed with a gas-oxygen torch and measures about 50 mm in length after sealing (Figures 1 and 2).

Some lyophil machines use larger ampoules that may contain 1 ml of cell suspension. These larger tubes may be initially frozen, but do not need immersion in a freezing bath because evaporation of this larger volume is adequate to keep the preparations frozen. Depending on the design, the larger ampoules may be sealed with a gas-oxygen torch or by inserting a rubber stopper into the ampoule while it is still under vacuum.

An ampoule of each strain lyophilized should be tested for viability within a few days of processing. This is done by suspending the lyophilized pellet in liquid growth medium and by determining if growth occurs. Rough quantitation of viability can be made by sneaking a loopful of the suspension onto an agar plate. Many microorganisms lyophilize well but only a few percent of the original cell population survives the process. Nonetheless, there is little evidence that certain nuclear genotypes preferentially survive, although plasmids may sometimes be lost. Lyophilized strains generally survive for many decades, though there are exceptions and the cultures should be checked periodically for viability. Lyophilized cultures are usually stored in a refrigerator at 4 – 5°C , as frozen storage seems unnecessary (Figure 3).

L-drying

A process termed L-drying has been successfully used by several large culture collections in Japan. The process is similar to lyophilization with the exception that cells and cryoprotectant are dried more slowly under vacuum and do not freeze. L-dried ampoules are sealed in the same manner as lyophilized preparations.

Figure 1 Lyophilization of cultures. As described in the text, ampoules containing microbial cells and a cryoprotectant are placed on the manifold of the lyophil apparatus and are freeze-dried. The ampoules are being sealed with a gas-oxygen torch. A dry ice–ethylene glycol bath (covered) for freezing the ampoules is at the base of the manifold. A vacuum pump is on the left. The vertical metal tube behind the manifold on the left is a dry ice moisture trap to prevent contamination of the vacuum pump with water from drying cultures. A vacuum gage is immediately behind the manifold base. Photograph by Don Fraser, National Center for Agricultural Utilization Research.

Figure 3 Refrigerated storage of lyophilized cultures. Ampoules of each strain are placed in plastic boxes arranged in numerical order. Photograph by Don Fraser, National Center for Agricultural Utilization Research.

Liquid Nitrogen Preservation

Some microorganisms do not survive lyophilization or L-drying. The most common alternative, which is generally the most effective, is frozen storage at very low temperatures. While storage in -80 and -125 °C mechanical freezers is often satisfactory, storage at still lower temperatures is preferable. The choice is the vapor phase of liquid nitrogen, which is about -180 °C. Liquid

nitrogen at atmospheric pressure has a slightly lower temperature of -196°C (-320°F), but a concern with immersion storage is that ampoules might leak and when thawed, the trapped liquid nitrogen will expand to gas so rapidly that the ampoule explodes, potentially causing serious injury to the person thawing the sample.

The general procedure for preparing microorganisms for liquid nitrogen storage is to suspend cells from an actively growing culture in a cryoprotectant such as 10% glycerol. Usually 1 ml of suspension is placed in a 2 ml cryoampoule (Figure 2). Ordinarily, the ampoules are transferred to a storage box in the liquid nitrogen freezer and allowed to undergo uncontrolled freezing (Figure 4). Occasionally, the freeze rate needs to be controlled to ensure high cell viability, which is often greater than 90%. Controlled freezing can be accomplished very simply by putting the ampoule in a plastic foam box, which is then placed in the liquid nitrogen freezer. If this process is not adequate, freezing may be controlled by using commercially available devices that have a programmable freezing rate. To save space, some laboratories use short sections of plastic soda straws as cryoampoules. Straws are cut into sections about 2 cm long, the bottom is heat-sealed with flamed forceps, and the straws are then sterilized by autoclaving. After filling with a cell suspension, the open end of the straw is then heat-sealed with flamed forceps. Microorganisms stored in liquid nitrogen vapor usually remain viable for many decades, and perhaps longer.

Distribution of Cultures

Culture collections almost never charge for depositing strains in their general collections and, in fact, collections often contact persons with new and interesting cultures in order to remain current. Patent culture deposits, however, are another matter, and culture collections charge a fee for patent culture deposits because of the need for more frequent viability determinations and more stringent international administrative requirements.

Many collections charge a fee for distribution of cultures, but some collections, such as the ARS Culture Collection, do not charge for distribution of most of the cultures maintained. Nonetheless, most collections must charge a fee for culture distribution because of the expense of maintaining the strains, replenishment, and shipping. Fees vary among collections, but the fees often do not completely cover operating costs because of the expense of maintaining cultures that are seldom distributed, but which are important for various scientific reasons.

Distribution of cultures from patent collections is governed by a variety of national and international laws and regulations. In the United States, patent cultures cannot be distributed until the subject patents issues or the depositor agrees to distribution, but in Europe, publication of a national patent application can trigger strain release. Requirements of the Budapest Treaty must be taken into consideration, and many collections require that requests for cultures deposited under the Budapest Treaty be received as signed hard copy letters. The collection must then verify that the culture can be distributed, and the depositor must be notified that the culture was requested and by whom.

In recent years, many collections have required that a Materials Transfer Agreement (MTA) be implemented between the collection and the requestor, although some collections do not require an MTA because it is felt that this might in some way limit usage of the strain for scientific and industrial development. Collections that impose an MTA argue that this prevents redistribution of the strain and also ensures that the collection has no liability if the strain is misused. MTAs should not be used to extract revenue from an invention involving the requested strains unless culture collection scientists were active participants in the discovery.

Shipment of cultures is governed by a variety of national and international laws and regulations, and some of these regulations have developed in recent years because of the threat of global bioterrorism. Within the United States, shipment of plant and animal pathogens requires a permit from the USDA Animal and Plant Health Inspection Service (APHIS). Permits for shipment of human pathogens may also be required from the US Public Health Service. Other countries often have their own specific regulations, and shipment of plant and animal pathogens between countries often requires special permits. These requirements should be taken seriously because failure to comply can result in closure of laboratories, large fines, or even incarceration. Shipment of cultures can also be governed by the Convention on Biodiversity, also known as the Rio Treaty. Here the concern is that part of a country's national heritage, that is, unique microbial germplasm, will be exploited by outside parties without due compensation. Consequently, before novel or other strains are shipped between countries, the requirements of the Rio Treaty must be known.

Conclusions

Culture collections play a major role in modern societies. Provision of cultures for medicine, agriculture, and other areas of science has proven essential to disease prevention and control as well as for developments in biotechnology. The taxonomic expertise that is common to culture collections has led to identification of new pathogens and has promoted advancements in ecology, studies in biodiversity, and other areas of science needing accurate identification of microorganisms.

Glossary

carrier An individual who harbors and may excrete virulent bacteria while remaining free of symptoms of the disease.

cyclogeny A theory, widely held in the 1920s and 1930s, that asserted that bacteria in cultures go through stages of a life cycle in which the bacterial cells may undergo changes in shape, size, staining, and biochemical properties.

endotoxin Molecules contained within the bacterial cell, but which when released by lysis of the cell can exert toxic effects on the host cells by a variety of biological mechanisms.

flagellum A flexible fiber-like structure on the surface of some bacteria. Flagellar movement is responsible for bacterial motility. The flagellum is driven by an internal cellular structure, the 'motor', which is powered by a proton gradient across the cell membrane.

Peyer's patches Localized lymphoid tissue in the small intestine of mammals.

Defining Statement

This chapter focuses on the historical aspects of typhoid fever in its clinical manifestations, epidemiology and etiology.

Background and History

Typhoid is the classic 'enteric fever' which begins with malaise, anorexia, and headache, followed by high fever and abdominal tenderness and distention. Rose spots appear on the skin. Patients may become delirious, the 'typhoid-state' for with the disease is named (typhus/ τυφλος: stupor), have shock from intestinal hemorrhage, and die. It often occurs in epidemics, especially under conditions of poor sanitation such as in military camps and after widespread natural disasters. Its symptoms and epidemiology overlap with that of typhus (camp fever), so typhoid had been confused with this rickettsial disease for much of its history. The name, typhoid, implies a 'typhuslike' condition, and these two diseases have been clearly delineated only since the mid-nineteenth century.

The typhoid organism infects only humans and chimpanzees, entering the body through the alimentary tract. In the sick individual the organisms are usually found in the spleen, bone marrow, lymphoid tissue associated with the gut (Peyer's patches), and almost always in the gall bladder. Much of the pathology and the symptoms of typhoid are the result of endotoxin which is released upon lysis of the bacteria. The typical incubation period is 7–14 days. Mortality in untreated cases is about 10%; 75% of these have intestinal hemorrhage or perforation. About 3% of clinically recovered patients still excrete the typhoid organism in the feces after 1 year and are designated as carriers.

In England, Huxham (1739) in his 'Essay on Fevers' described the Plymouth epidemic of 1737, and he distinguished between putrid typhus (*febris putrida*) and slow nervous fever (*febris nervosa lenta*) that is now recognized as typhoid. As disease nosology evolved, and the concept of specific disease entities developed, by the nineteenth century typhoid and typhus were being recognized as diseases with distinct clinical features. The American physician and medical educator, Nathan Smith, provided the classic description of typhoid in 1824 in his essay 'A Practical Essay on Typhous Fever', in which he recounted his observations of what is clearly typhoid in the Connecticut River Valley in New England. The great Parisian clinician Pierre-Charles-Alexandr  Louis named the condition *fi vre typho ide* in his major work on the disease in 1829. Sch nlein (1839) in Germany distinguished *Typhus exanthematicus* (typhus) and *Typhus abdominalis* (typhoid), terms which became established in the German literature.

The English physician William Budd (1811–73), who studied under Louis at the La Pitie' hospital in the 1830s, saw outbreaks of typhoid fever in his rural general practice and by careful observations on the spread of the disease concluded that typhoid was spread from person to person. This put him in the camp of the 'contagionists' who were vigorously opposed by the 'anticontagionists', physicians who favored the miasma theory of disease for diseases such as typhoid. Budd published his first detailed 'natural history' of typhoid (what would now be called an epidemiological study) in 1856. He described similar outbreaks in later publications, and even before the rise of bacteriology, Budd concluded that typhoid was spread by fecal contamination of water and milk. He also proposed that a convalescent patient could still be a source of contagion. Budd was an enthusiastic advocate of

This article is a reprint of W.C. Summers, Typhoid, Historical, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 97–99.

disinfection, both of drains and of privies as well as water supplies. This work on typhoid and its waterborne dissemination was contemporaneous and apparently independent of parallel work by John Snow on cholera in London.

Carl Joseph Eberth described the typhoid organism in tissues of patients in 1880, and Georg Gaffky isolated and grew this organism in 1884. Since the typhoid bacterium is relatively easy to grow in culture, soon many different bacterial isolates were found in typhoid-like cases, both in humans and in other species. For example, in 1888 Gaertner isolated what is now designated *Salmonella enteritidis* from a patient who had eaten contaminated meat, and shortly thereafter Durham and de Noëble isolated *Salmonella typhimurium* from gastroenteritis patients who also had eaten contaminated meat. The classification of these early isolates was based on the disease entity (*Salmonella choleraesuis*, i.e., hog cholera), the geographic place of isolation (e.g., *Salmonella montivideo*, *Salmonella newport*), or the name of the investigator (*Salmonella schottmülleri*). In 1896 Grünbaum and Widal independently observed that serum from infected or recovered patients could agglutinate dead typhoid bacteria, and this test (Widal reaction) became the basis for a serological diagnosis of infection as well as a tool to study *Salmonella* pathogenesis.

Taxonomy and Classification

The early nomenclature of the typhoid bacillus is even more confusing and inconsistent as that of most bacteria. The typhoid organism was variously called *Bacillus typhosa*, *Bacterium typhosum*, *Eberthella typhosa*, *Salmonella typhosa*, and most recently *Salmonella typhi*. The genus is named in honor of Daniel Elmer Salmon (1850–1914), the first director of the Bureau of Animal Industry of the US Department of Agriculture and one of the founders of bacteriology in America. Salmon investigated hog cholera and, along with his protégé Theobald Smith, identified the hog cholera bacillus (*S. choleraesuis*), long believed to be the cause of hog cholera (later found, however, to be caused by a filterable virus).

When it was found that individual isolates could be distinguished serologically from one another, classification of the typhoid bacillus and its relatives was revised and based on the antigenic reactivities of a particular isolate. Some strains grew in more diffuse colonial form on surface cultures, and this growth form had come to be described as similar to the appearance of ‘breath’ (perhaps the water condensate) on the agar surface. These strains shared antigenic properties termed H-antigens (*Hauch*: breath). Later it was recognized that this diffuse colony morphology results from the motility of the individual organisms and that the H-antigens are associated with the flagella of these strains. The antigens of the strains without H-antigens were designated as O-antigens (*Ohne*: without), and are now recognized as ‘somatic’ antigens, belonging to the ‘body’ of the bacterium. A third category of serological reactions was believed to be related to virulence of the organism in experimental infections, and these antigens were designated as the Vi or virulence antigens. The H-antigens were observed to vary with the culture conditions, and this two-state variation was interpreted in terms of the cyclogenic theories of the interwar period as characteristic of different growth phases of the culture, hence the concept of ‘phase variation.’ Once the H-antigens were understood in terms of the flagellar antigens and structure, phase variation was reinterpreted as a problem in flagellar biosynthesis and regulation.

Fritz Kauffmann (1937) and Philip B. White (1926) studied the antigenic structures of the typhoid and typhoid-like bacteria in detail, and the Kauffmann–White system of classification became standard. This system of classification of the genus *Salmonella* employs the H, O, and Vi antigenic specificities to identify a particular isolate. In 2005, the International Commission on the Nomenclature of Prokaryotes designated the ‘type’ culture for the genus *Salmonella* as *Salmonella enterica*. The species includes over 2300 serotypes, many of which were formerly designated as different species, for example, *S. choleraesuis*, *S. typhi*, *Salmonella paratyphi* A, and *S. typhimurium*. The variants are termed serovars, for example, *S. enterica* serovar Typhimurium.

Prevention and Treatment

Although vaccines for typhoid have been in use for a long time, it was only in the 1960s that definitive evidence of their effectiveness was obtained through studies on human volunteers. The best vaccine preparations give over 90% protection for at least 3 years against challenges with doses of typhoid similar to that expected in contaminated water supplies. Higher challenge doses, however, can overcome the vaccine-induced immunity and cause disease. Chloramphenicol (discovered in 1948) was the first effective drug to be used in typhoid, and it was followed by the newer penicillin derivatives as treatment for typhoid and other related *Salmonella* infections.

In addition to vaccines and antibiotics, however, the most effective means to prevent and control typhoid have been sanitary treatment of sewage and establishment of clean drinking water supplies.

Epidemiology

The epidemiology of typhoid, as exemplified by the work of William Budd, has been of great interest, both for medical and for sociological reasons. Based on epidemiological evidence, Robert Koch suggested that new cases of typhoid could come from convalescents long after the disease disappeared, and in support of this assertion, Drigalski (1904) isolated typhoid bacteria from individuals with no signs of illness. Observations such as these led to the concept of the healthy carrier of disease. Soon it was recognized that the gall bladder was a common site in which to find bacteria in these carriers, and ways were sought to eradicate the asymptomatic infections in order to eliminate the carrier state. Gall bladder removal (cholecystectomy) was a favored treatment.

Less drastic approaches such as chemotherapy and various disinfectants were tried without success. Food contamination, usually by flies in summer, but sometimes by food handlers, led to the notion of the carrier as a danger to society. Quarantine and sometimes long-term detention of suspected or proven carriers were justified in the cause of protecting the public from contamination. Probably the most notorious and egregious case was that of Mary Mallon, an Irish immigrant domestic worker in New York, who seemed resistant to treatment and who was deemed uncooperative by the New York City Public Health authorities. As 'Typhoid Mary' she was *de facto* incarcerated in Riverside Hospital on North Brother Island in the East River by Manhattan for many years. Indeed, the term 'Typhoid Mary' has become generic for a carrier of a dangerous disease who is uncooperative in preventing its spread.

Typhoid and its agent played another role in the American legal system when the city of Chicago constructed a drainage canal to help channel Chicago sewage from the Chicago river into the Mississippi River watershed. Downstream, the city of Saint Louis, Missouri was the potential recipient of the diverted sewage. Worried about typhoid outbreaks from Chicago, St. Louis went to court to block the Chicago plan. This case was the first in US history in which the new science of bacteriology was accepted as expert testimony in court.

In circumstances of social disruption, such as wars, civil unrest, famine, or natural disasters which affect water and sewage systems, typhoid is still a major health problem. However, immunization, antibiotics, and sanitary measures have reduced the US typhoid mortality from 26 per 100 000 in the period 1906–10, to about 500 in the entire US population in 1967, to a few sporadic cases at present.

Defining Statement

This article focuses on the historical aspects of rickettsial diseases, the causative agents and their arthropod vectors, and the diagnosis of epidemic and murine typhus, Rocky Mountain spotted fever (RMSF), Mediterranean spotted fever (MSF), African tick bite fever (ATBF), and other rickettsioses.

Introduction

Rickettsial diseases existed since antiquity and have had great effects on the history of human populations. Massive population movements, poor hygiene, and famine favored the development of epidemics, and many wars and invasions were associated with or followed by outbreaks that included typhus. Typhus may cause more deaths than weapons during wartime. The Napoleonic wars were examples of the terrible consequences of a combination of war and diseases, and thousands of soldiers succumbed to typhus, as proven recently by molecular biology. Rickettsioses occurred not only in the history of the military, it has been a continuing threat to public health too.

The serious danger of rickettsial diseases stimulated remarkable medical research and clinical observations, which clarified their specific etiology, mode of transmission, pathogenesis, therapy, and means of control. Because of their unique biological characteristics, such as small size, ranging to the limits of microscopic vision and beyond, ability to pass through a filter, inability to grow on bacteriologic media, and their obligate intracellular habitat in vertebrate and arthropod hosts, researchers had serious difficulties in identifying rickettsial agents. Moreover, the rickettsial agents were treated as dangerous organisms due to their aerosol transmission, low infectious dose, and high risk-associated morbidity and mortality. Several microbiologists in the laboratory and physicians, particularly in the preantibiotic era, died of rickettsial infection like Howard Ricketts and Stanislav von Prowazek (Table 1).

A remarkable progress was made in 1904 when Wilson and Chownin proposed related hypothesis on the transmission of rickettsia by tick bite. In 1909, Nicolle showed the louse transmission of typhus. In 1938, Cox demonstrated that rickettsiae could be cultivated in the yolk sacs of chick embryos. In 1948, it was demonstrated that broad-spectrum antibiotics were shown to be specifically and therapeutically effective. Tetracycline and chloramphenicol are the currently used antibiotics of choice in treating rickettsial diseases and have not been challenged since their discovery. The rickettsial scientific field has undergone significant evolution at the epidemiological, microbiological, and molecular levels in the past 20 years. Currently, the *Rickettsia* genus contains 24 recognized species, in contrast to three human pathogens and five endosymbionts as mentioned in the 1922 Brumpt list.

This article is a reprint of C. Socolovschi, D. Raoult, Typhus Fevers and Other Rickettsial Diseases, Historical, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 100–120.

Table 1 The great scientists who died of typhus fever

1744–1814	Johann Bartholomäus (Barthel) von Siebold, the ancestor of the “Würzburg family” of physicians and scientists
1784–1850	Zachary Taylor, president of the United States
1871–1910	Howard Taylor Ricketts, researcher
1875–1915	Stanislaus von Prowazek, zoologist and parasitologist
1870–1915	Hugo Lüthje, scientist
1858–1915	Georg Cornet, researcher, scholars of Robert Koch
1874–1915	Georg Jochmann, physician of the Department of Infectious Diseases, Berlin
1870–1916	Artur Pappenheim, Doctor Habilitatus, professor haematologist
1876–1916	Paul Römer, the professor of Hygiene at the University of Halle
1890–1921	Wolfgang Gärtner, lecturer at the University of Kiel
1866–1922	Arthur William Bacot, entomologist
1879–1922	Edmund Weil, researcher

In this article, we review the milestones of historical aspects of rickettsial diseases, discovery of the infectious agents, their vectors and mechanism of transmission and reservoir, and the major technological developments that have facilitated the study, control, and treatment of rickettsiae and rickettsial diseases.

Rickettsia and Human Rickettsioses

The term ‘rickettsia’ applies only to arthropod-borne bacteria, belonging to the genus *Rickettsia* within the family Rickettsiaceae of the order Rickettsiales. *Rickettsiae* are small Gram-negative microorganisms that grow in association with eukaryotic cells. These bacteria are described as obligate intracellular organisms that retain basic fuchsin when stained by the method of Gimenez. Rickettsial cells divide by binary fission for multiplication and can be cultivated in cell cultures, embryonated eggs, or susceptible animals. Members of the *Rickettsia* genus are closely related phylogenetically and have a high degree of 16S rDNA sequence homology to each other.

Historically, cross reactions of patient’s sera with somatic antigens of strains of *Proteus* OX19, OX2, and OXK were used to classify rickettsial isolates into three groups, namely, the spotted fever group (SFG), the typhus group (TG), and the scrub TG. Subsequently, the scrub typhus species *Rickettsia tsutsugamushi* was reclassified within the genus *Orientia*. Other phenotypic criteria that have been used to describe *Rickettsia* species include the geographical distribution of the strain, the arthropod vector, pathogenicity in humans, mice, and guinea pigs, optimal culture temperature, time for plaque formation, size of plaques, growth in embryonated chicken eggs, and hemolytic activity. Recently, guidelines were proposed to classify rickettsial species and the diseases they cause.

Presently, the genus *Rickettsia*, with 24 currently validated species, is divided into two main groups: the TG with *Rickettsia prowazekii* and *Rickettsia typhi* and the SFG that accounts for most tick-borne rickettsiosis and also *Rickettsia felis*, which is the agent of flea-borne spotted fever and *Rickettsia akari* is the agent of Rickettsialpox transmitted by mite (Table 2). Rickettsial organisms are mainly transmitted to humans by bites from infected arthropods. However, infections from aerosols of infected insects, feces, and blood transfusions have also been described. Besides the known pathogens, many other rickettsial strains have been found in arthropods, in particular ticks, but their roles as human pathogens have yet to be determined. New developments in the epidemiologic profile of rickettsioses include the emergence of spotted fever rickettsioses due to *Rickettsia rickettsii* in Argentina, Brazil, Columbia, and the United States; identification of other *Rickettsia* species in ticks in South America and Mexico; and outbreaks of louse-borne typhus in Burundi, Russia, Peru, and Algeria.

To date, 16 known rickettsioses are recognized and represent a global problem. Rickettsioses are seasonal outbreaks and the arthropod host determines their epidemiology and geographic distribution. The clinical presentation of rickettsial diseases can vary from mild to very severe, with the case fatality for highly virulent rickettsiae ranging from 2 to >30% (Table 3). The main clinical signs include fever, headache, rashes that are maculopapular or sometimes vesicular, inoculation eschars at the site of the arthropod bite, and localized lymphadenopathy. The severity of the diseases varies with the pathogen virulence and the host factors. The main pathologic mechanism in rickettsioses is vasculitis following infection of the endothelial cells.

Rickettsiae represented a paradigm of reductive evolution. The reconstruction of ancestral genomes, using seven *Rickettsia* genomes that inferred the origin and fate of the genes found in today’s species, indicates that their last common ancestor contained more genes, but already possessed most traits associated with cellular parasitism. The obligate endocellular microorganisms tend to evolve faster as a consequence of reduced effectiveness of selection, and suggest a major role of enhanced background mutation rates on the fast protein divergence in the obligate intracellular α -proteobacteria.

Epidemic Typhus

Epidemic or louse-borne typhus, caused by *R. prowazekii*, transmit by the human body louse, which lives in clothes and multiplies rapidly during cold weather and in unhygienic places. Its prevalence reflects the low socioeconomic status of certain members of a

society and rises during war, in poor countries, and in homeless people in rich countries, including the United States and Europe. The recent outbreak in a refugee camp in Burundi, which involved thousands of cases (mortality rate >10%), and other cases reported in Rwanda, Russia, Peru, the United States, and Algeria are reminder that epidemic typhus can reemerge as a result of a catastrophic breakdown of social conditions.

Table 3 Effect of specific antibiotics in the course of major rickettsioses

Disease	Untreated Average duration of the fever (days)	Mortality (%)	Treated Average duration of the fever after treatment (days)	Mortality (%)
Rocky Mountain spotted fever	16	21	3	0
Epidemic typhus	14	30–40	2	0
Murine typhus	12	2–5	2	0
Scrub typhus	14	15	1	0

The clinical onset of epidemic typhus is usually abrupt after an incubation period of about 14 days. Classical epidemic typhus is the most severe rickettsial disease, with symptoms including a high fever, headache, chills, myalgias, conjunctival injection, and rales. Erythematous macules (2–6 mm) appear most often on the trunk on day 5 and later on the extremities; the face, palms, and soles are usually spared. The characteristic rash of typhus is also the origin of more descriptive names, such as spotted fever in English, Fleckfieber in German, and thyphus exanthématique in French. Myocarditis, pulmonary involvement, severe neurologic complication, and gangrene of the distal extremities may occur in severe cases. Without the availability of antibiotics, the disease is fatal in 13–60% cases (Table 3).

Flying squirrel-associated typhus (sylvatic form) has been less severe (fever, headache, maculopapular rash, confusion, and myalgia), with no fatalities records. Once infected with *R. prowazekii*, convalescent patients maintain the infection for all their life, and with weakening immunity recrudescence typhus, Brill–Zinsser disease may occur. The symptoms of recrudescence typhus are less pronounced, and the associated mortality rate is <1%. Patients with this disease could serve as a longterm source of *R. prowazekii*, permitting transmission of rickettsiae via lice to occur months to years after the primary infection, and may play the mechanism for the dissemination in many parts of the world.

Historical Aspects of Epidemic Typhus and Brill–Zinsser Disease

Typhus, the ‘spotted fever’ of the sixteenth century in England, the ‘gaol fever’ of the eighteenth, and the ‘Irish fever’ of the mid-nineteenth centuries, has a long and distinguished history intimately associated with the social upheavals caused by war and famine. Greek, etymology of typhus, meaning smoky or hazy, was originally applied by Hippocrates to the confused states of mind frequently associated with high fevers. Some historians such as Haeser and Hecker contend that the disease was described by Thucydides during the Plague of Athens (430–425 BC), but recently typhoid fever was reported as the causing agent. The first account of typhus was recorded during the civil wars of Grenada 1489–90, when typhus was introduced in Spain by soldiers from the island of Cyprus (Table 4). The distribution of typhus from Spain to Italy, France, and then northward continued in an almost uninterrupted succession of small outbreaks. The disease was described by several physicians such as Girolamo Fracastorius in 1546 in *De Contagione et Contagiosis Morbis*, referring to the Italian epidemics of 1505 and 1528 and distinguished it from plague; Girolamo Cardano in his book *De Malo recentiorum medicorum Ursu Libellus* in 1536; and by Von Zavorziz in 1676 in *The Infection of Military Camps*.

Villalba suggests that typhus was transported from Spain to the New World during the first half of the sixteenth century, but historical evidence suggests that typhus fever existed among South American natives in pre-Columbian days and recognizable epidemics occurred in Mexico before the arrival of Cortez at Vera Cruz in 1519. Moreover, there is a legend, credited by Bernal Diaz and by Nicolas Léon, that typhus destroyed the Toltec city of Tollan in 1116 AD. The description of typhus fever in Mexico was done by missionaries in 1545. Toward the end of the sixteenth century, typhus killed more than 2 million native Indians in the Mexico highlands. It is tempting to speculate that typhus was born in the chance meeting of an American rickettsia and a Spanish louse.

A century after the Thirty Years’ War (1618–48), when the epidemic typhus spread in Europe (Germany lost three-fourth to one half of her total population), Huxham, in 1739, made the first distinctions between typhus and typhoid (Table 5). Boissier de Sauvages confirmed this in the eighteenth-century in France and called it exantematic typhus. In 1836, William Gerhard of Philadelphia clearly distinguished between typhus and typhoid fevers based on postmortem findings of six patients revealing the remarkable absence of ulceration of Peyer’s patches, contrary to observation of typhoid. By the 1860s, the physicians distinguished typhus from another louseborne disease, relapsing fever (*Borrelia recurrentis*), while problems of diagnosis remained. Later, Bacot established that trench fever and typhus were different diseases; the former was caused by *Bartonella quintana* and the latter by *R. prowazekii*. This was tragically confirmed by a typhus infection acquired by him in 1922.

In 1909, Nicolle showed the transmission of the disease through the blood of a typhus patient to a chimpanzee and from the chimpanzee to a macacus monkey. The disease was then transmitted from macacus to macacus via the louse. In 1911, the typhus patient transmitted the infection to the guinea pig. Although fever was the only sign of the disease, the guinea pig remained for many decades the most useful experimental animal. Later, Wobach detailed the clinical observations and the human histopathology, and the effect of *R. prowazekii* infection on guinea pigs.

During 1896–1910, Nathan Brill, in New York, studied 221 febrile patients whose illness reminded him of typhus rather than typhoid fever, in spite of protestations of his colleagues. Negative blood cultures and Widal reactions led him to call it an illness of

Table 5 Milestones of suspected outbreaks of epidemic typhus

<i>Years</i>	<i>Country</i>	<i>Number of deaths</i>
1489–90	Civil wars of Grenada, Spain	17 000 Spanish soldiers
1528	Naples, Italy	21 000 French soldiers
1542	Hungary	30 000 German and Italian soldiers
1545	Mexico	2 million native Indians
1552	Metz, France	10 000 soldiers
1557–59		10% of the English population
1618–49	The Thirty Years War, France (1628)	One half of total population of Germany 60 000 deaths in Lyon and 25 000 Limoges
1756–63	The Seven Years War, Europe	Thousands????
1812	Napoleon's invasion of Russia (confirmed by PCR assay)	550 000 French soldiers 61 964 Russian soldiers
1813–14	Europe	2 million people throughout Europe 250 000 people in Germany
1816–19	Ireland	700 000 people
1847	Canada	20 000 Irish immigrants
1854–56	Crimean war	134 000 soldiers
1914	Australian invasion in Serbia	150 000 Serbs and 30 000–60 000 Austrian prisoners
1917–25	World War I and Russian Revolution	3 million Russian people (30 million cases) 150 000 Serbs and 60 000 Australian prisoners
1942	Egypt	23 000 cases
	French North Africa	77 000 cases
1945	World War II	17 000
1989	Russia	29 cases
1997	Burundi	43 345 cases

unknown cause; it was a mild form of typhus fever, later named as Brill's disease. In 1933, Zinsser and Castenada isolated *R. prowazekii* from these cases. Through careful analysis of epidemiological data, Zinsser concluded that it is a recrudescent typhus case and it served to maintain endemic prevalence of *R. prowazekii* by bridging breaks in the chain of man– louse–man propagation. Zinsser's hypothesis was confirmed by Murray in 1950.

Infectious Agent: *Rickettsia prowazekii*

In 1910, Ricketts, while working on the etiology of typhus fever in Mexico, speculated that the agent of typhus had the same morphology of bubonic plague and Rocky Mountain spotted fever (RMSF) organism. He described bacillary or pleomorphic bodies, with bipolar dark staining and intervening pale areas, in the blood of patients suffering from typhus and in the dejecta of lice that had fed on these patients. However, these descriptions do not fit with our current knowledge and represent something else. In 1911, Charles Nicolle isolated these bacteria from guinea pig. In 1913, Hegler and von Prowazek described appearances of neutrophilic leucocytes in 51 typhus cases and in a smear from louse, which they believed to be microorganism.

In 1914, in Istanbul, and in 1915, in eastern Germany, Rocha Lima and Stanislaus von Prowazek confirmed the observations of previous workers, and together they described *R. prowazekii* (Figure 1). In 1916, Rocha Lima grouped the microorganisms in the order Rickettsiales and named the agent of typhus *R. prowazekii* after Ricketts and his deceased friend von Prowazek. In the same year, Edmund Weil and his English associate Arthur Felix showed that a strain of *Proteus* bacillus was agglutinated by the sera of typhus patients. Some European bacteriologists declared that the *Proteus* bacillus was the 'exciting organism' of typhus, while others argued that *Proteus* and the typhus virus were simply variants of the same organism. The debate about infectious agent was resolved in 1937 by Herarld Cox with the development of the tissue culture technique. Later, cross adsorptions showed that there was a common cross-reacting epitope among *Legionella bozemanii* Wiga, *Rickettsia* TG, and *Proteus* OX19, due to a common lipopolysaccharide antigen.

In 1998, the complete genome sequence (1.1 Mb) of *R. prowazekii* showed 834 protein coding genes, contains the highest proportion of noncoding DNA (24%) detected so far in a microbial genome and the phylogenetic analysis proved new evidence of an evolutionary relationship between rickettsiae and intracellular mitochondria.

Disease Vector: The Human Body Louse (*Pediculus humanus corporis*)

In 1740, James Lind, a physician observed that typhus was carried on the bodies of men, on clothes; but only in 1909, Charles Nicolle discovered the role of lice in transmission of typhus, later receiving the Nobel Prize (Figure 2). By 1903, Tunis was full of typhus patients; Nicolle observed that patients infected others on the street and their clothing was infectious. After the patients had a hot bath and were dressed in hospital clothing, they ceased to be infectious. Later, he fed uninfected lice on an experimentally infected bonnet monkeys (*Macacus sinicus*) and then transferred the lice to uninfected monkeys that later developed typhus. This accomplishment became a powerful impetus for the establishment of delousing procedures. In the same year, Ricketts and Wilder confirmed these results in Mexico City and N. F. Gamaleia in Russia.

In 1916, Da Rocha Lima discovered that the *R. prowazekii* multiplied within the epithelial cells of the louse's stomach, which was confirmed by others researchers, such as Nöller, Töpfer, and Schüssler. In 1922, Wolbach observed that *R. prowazekii* escapes from alimentary tract through feces and they supposed that it may be introduced by scratching or by the mouth parts of the louse after becoming soiled with feces. They did not see rickettsia in the salivary glands or in the esophagus of louse. At that time, it was difficult to investigating lice as many were infected by *B. quintana* (*Rickettsia pediculi*). However, only in 1938, Starzyk demonstrated that patients are infected by the faces and not by the bite of the louse, and *R. prowazekii* could be transmitted to man by inhalation or in a conjunctive way. The role of lice as a vector of epidemic typhus has been studied in many countries, and in 2002, by using modern tools, an experimental model was established, which reproduces the natural infection of body louse.

The question of survival for *R. prowazekii* during interepidemic periods has led to several rather controversial hypotheses about reservoir. As suggested by Zinsser, after his study of 538 Brill's disease cases, the main reservoir appears to be in humans, because lice die of the infection and humans who contract typhus retain some rickettsiae for the rest of their life. This finding was confirmed by

Figure 1 *Rickettsia prowazekii* in the L929 cell culture (day 6) by Gimenez staining.

Figure 2 The human body louse, *Pediculus humanus humanus* (*P. h. corporis*).

Nicolle (1934), Giroud (1948), Mooser (1946), Willsch (1952), Gear (1952), and Murray (1951). In contrast, Reiss Gutfreund in 1956 found, in Ethiopia, *R. prowazekii* in domestic animals and their ticks. *R. prowazekii* was isolated from adult *Amblyomma variegatum* and *Hyalomma marginatum rufipes* and *Hyalomma truncatum* in Ethiopia. Transmission from experimentally infected larvae to nymphs took place in 50% of *A. variegatum* and *Amblyomma lepidum*. *R. prowazekii* was maintained for several years in experimentally infected *Ornithodoros moubata* and in *Ornithodoros papillipes*; however, adverse effect on *Dermacentor marginatus* and *Discoglossus pictus* ticks has been reported. Recently, *R. prowazekii* was detected by molecular detection and isolated by shell vial culture in *Amblyomma* ticks collected in Mexico.

Later, Dyer and Mooser found *R. prowazekii* in the fleas, and several experiments to infect fleas with *R. prowazekii* were reported. The head louse *Pediculus humanus capitis* is capable of maintaining *R. prowazekii* experimentally; its role in the transmission of this rickettsiosis is not well established. An extensive work by Ormsbee and McDade failed to support the hypothesis that an extrahuman reservoir of infection plays an important role in the ecology of epidemic typhus. The search was further stimulated by the isolation of *Rickettsia canadensis* from a pool of ticks taken from rabbit. While investigating the ecological niche of *R. canadensis*, Bozeman unexpectedly recovered several strains of *R. prowazekii* from flying squirrels (*Glaucomys volans volans*) that had been captured in Virginia and Florida. Later, it was found in their ectoparasites. Thus, the hypothesis of a widespread extrahuman reservoir of epidemic typhus was confirmed.

Diagnosis and Treatment of Epidemic Typhus: Historical Aspects

Serology: During the first two decades of the twentieth century, numerous attempts were made to cultivate the bacteria from the blood, urine, and stools of typhus patients. In 1910, Wilson reported the isolation of a coliform bacterium, designated *Bacillus U*, from stools and rarely from urine, and not from blood. His work demonstrated that the bacterium was agglutinated by sera of typhus patients to a titer 3–10 times greater than by sera from normal individuals or patients with other diseases. Comparable results were obtained in 1916, in Berlin, by Weil and Felix with a *Proteus* isolate from patients' urine. Other agglutination tests were suggested like agglutination with *Vibrio cholerae* by Cantacuzène (1919), with *Pseudomonas aeruginosa*, *V. cholerae* infection, *Bacillus prodigiosus*, and *Bacillus subtilis* by Violle (1920). Epstein and Morawitz named it 'the Weil–Felix test' in honor of the researchers, and it remained for many decades the chief tool for the serological diagnosis of the typhus fevers.

Staining rickettsiae: Rickettsiae stained poorly with the Gram stains, most of early observations were made on smear and sections stained with Giemsa. In 1930, Castenada substituted, to some advantage, the azur II and eosin of Giemsa's with methylene blue and safranin.

More successful was the procedure introduced in 1937 by Macchiavello using basic fuchsin (rickettsiae retain the red stain), following decolorization with citric acid and counterstaining with methylene blue. In 1964, Gimenez changed the methylene blue with malachite green. This procedure has gained wide acceptance until now (Figure 1).

Culture: In 1937, Kligler and Aschner proposed the same technique for cultivating *R. prowazekii* such as the one presented earlier by Nigg and Landsteiner for murine typhus using Maitland cultures in tissue cultures. Zinsser found that greater yields of rickettsiae could be obtained on agar cultures with the same constituents. In later experiments, he used Kolle flasks for the mass cultivation of rickettsiae from minced tissues obtained from mouse and chick embryos. Herald R. Cox's discovery of using the yolk sacs of chick embryos for cultivating rickettsiae in 1938 had an enormous impact on rickettsial technology, paved the way for a new generation of vaccines and diagnostic reagents, and facilitated studies of rickettsial susceptibility to chemotherapeutic agents and rickettsial physiology. In the following years, *R. prowazekii* was cultivated in chick fibroblast cell culture, in cotton rat macrophages, in guinea pig macrophages, L929 cell line mouse, vero cells (kidney epithelial cells extracted from African green monkey), and NIAS-AeAI-2 insect cells. Recently, *R. prowazekii* was isolated from a blood sample from a patient by the shell vial cell culture technique using human embryonic lung fibroblasts.

Control and eradication: The first prevention method used for the patients with epidemic typhus was double delousing process, more complete than that practiced on admission to the hospital using kerosene and 'lightwood oil'. This method was used since eighteenth century by James Lind in America and later by all physicians after Nicolle discovery. Dichloro diphenyl trichloroethane (DDT), a poisonous powder for insects, was used in Mexico, Algeria, Italy, and Egypt for delousing. In 1988, Darby proposed a protocol of powder dusting of the entire clothing with 10% DDT, 1% malathion, or 1% permethrin dust, but a resistance of lice to DDT was detected in Korea and Japan. A standard treatment protocol with 1% permethrin has been created by WHO in 1993. Because treatment should be repeated every week, of 3–5 tons of powder is required to treat 100 000 people on one occasion. In 1987, Strong and Brown sowed the therapeutic efficacy of ivermectin to eradicate lice.

Treatment: In 1919, Danielopolu recommended to use strophanthin or chlorine injection for typhus treatment. Some investigators employed large doses of the serum of convalescent. Digitalis or strychnia was given for possible supportive effect in most cases, and in case of a collapse camphor or caffeine. Preantibiotic chemotherapy of rickettsial diseases was dominated by *p*-aminobenzoic acid (PABA), discovered in 1942 by Snyder, and separately in 1944 by Greiff. In 1951, Snyder and Davis showed that the growth of rickettsiae is inhibited by PABA and requires *p*-hydroxybenzoic acid (POB); later, Weiss isolated PABA-resistant mutants of *R. prowazekii*, suggesting a role of POB in rickettsial biosynthesis.

The newly discovered antibiotic compounds, namely, the tetracyclines family and chloramphenicol changed the natural history of epidemic typhus. Initial clinical trials, carried out by Payne and Smadel, demonstrated the effect of chloramphenicol on patients ill with epidemic typhus. Chloramphenicol treatment in recrudescing typhus fever (Brill's disease) produced defervescence in approximately 4 days. Now, recommended treatments for epidemic typhus are doxycycline and chloramphenicol. Therapy for a minimum of 5 days and at least 2–4 days after defervescence should be provided to preclude relapses, especially with early treatment. In case of an outbreak, a single 200-mg oral dose of doxycycline is extremely efficient.

Vaccination and prevention: One of the earliest protective measures for typhus was consuming human lice. The value of this procedure is undocumented. Based on the protocol of RMSF vaccines, Rudolph Weigl developed, in 1930, a similar vaccine against epidemic typhus from the intestine of experimentally infected lice. Initially, more than 100 infected lice were needed to produce a single dose of vaccine; later 90 lice provided three doses of the vaccine. This vaccine was produced on a large scale in Weigl's laboratory before World War II in Poland and was used in China (1936, 1943), Ethiopia (1939), and other countries. After discovery of cultivation of *R. prowazekii* in embryonated chicken eggs, it was possible to produce very large quantities of live Rickettsiae, inactivated by 1.5% solution of phenol. A total of 5–6 millions of individuals were vaccinated against typhus during German occupation in the eastern zone of war operations. Two additional attempts of inactivated vaccine production deserve to be mentioned, one in the guinea pigs on a vitamin-deficient diet or by X-ray radiation made by Zinsser and Castenada in 1932 and the E strain vaccine reported by Fox in 1956, as they provide information on the biology of rickettsiae. The isolation of vaccine strain E, originated from a 1941 typhus case in Madrid, was passed routinely into eggs and reduced virulence for guinea pigs after the 11th passage. Extensive field trials were conducted in Peru and Burundi with strains passed into eggs at least 256 times.

Murine Typhus

Murine typhus, caused by *R. typhi*, was found throughout the world, and found to be prevalent in tropical and subtropical seaboard regions, where the most important rat reservoirs (*Rattus* spp.) and flea vectors (*Xenopsylla cheopis*) (Figure 3) are found, during warm months of year. It is difficult to establish the true incidence of the disease, and the number of reported cases does not reflect the true prevalence, because the patients usually mark a rather mild course and present with nonspecific symptoms. During the 1-month attack of Khmers in Thailand, the rate of murine typhus infection was 172 in 100 000 adults. Murine typhus may occur in travelers returning from endemic regions.

After an incubation period ranging from 6 to 14 days, the clinical manifestations were high fever, severe headache, chills, myalgia, weakness, and nausea. The rash described as macular (49%), maculopapular (29%), papular (14%), petechial (6%), and morbiliform (3%) is usually centrally distributed on the trunk, but also found on the extremities. Childhood murine typhus is often mild, with fever (100%) and rash (57%), lymphadenopathy (usually cervical (37%)), and severe headache (29%). Splenomegaly or hepatomegaly was less frequent findings (24 and 10%, respectively). Physicians practicing in or near *R. typhi* endemic areas need to consider murine typhus in the differential diagnosis with a febrile illness without a clear source of infection. Occasionally, patients develop some complications: central nervous system abnormalities (9.6%), renal insufficiency, hepatic insufficiency, respiratory failure are seen in older patients. There was one death in Maxcy's series of 114 cases, no deaths in a series of 180 cases by Stuart and Pullen, and 13 of 345 cases reported by Dumler.

Historical Aspects of Murine Typhus Disease

From the time of Brill's report, a sporadic typhus-like illness was designated throughout the world as 'endemic typhus' to distinguish it from the more serious classic louse typhus. Ricketts and several of the early researchers wondered if Mexican and European forms of typhus were the same diseases. Paullin made the first clinical description of a 'milder form of typhus' without mortality in 1913 in Atlanta (Table 6). In 1917, Neil noted that male guinea pigs inoculated with the blood of typhus patients in south Texas often developed a scrotal swelling and inflammation, along with hemorrhage beneath the tunica, similar to the lesions elicited by *R. rickettsii*. His results, confirmed in 1928 by Mooser, showed that the American and the European variety could be clearly

Figure 3 *Xenopsylla cheopis* femelle, the flea vector of endemic typhus.

Table 6 Milestones of murine (endemic) typhus

Discovery on murine (endemic) typhus: <i>Rickettsia typhi</i>	Authors
1913 First clinical description	Paullin
1920 The first name: <i>Dermacentroxenus typhi</i>	Wolbach and Todd
1921 Identification of <i>R. typhi</i> (guinea pig)	Mooser
1924 The first study on typhus	Stuart
1926 Isolation of <i>R. typhi</i> from the blood	Maxcy
1926 The first hypothesis of reservoir and vector of diseases	Maxcy
1930 Role of fleas and rat	Dyer and Mooser
1930 Tissue cultures (guinea pig tunica tissue)	Nigg and Landsteiner
1931 Mechanism of transmission	Ceder and Dyer
1940 Distinction of scrub typhus	Lewthwaite and Savor
2004 Genome sequence	McLeod MP <i>et al.</i>

differentiated by their reactions in the guinea pigs. These studies contributed in distinguishing the endemic from the classic typhus. It is difficult to differentiate when the workers were dealing with flea-borne typhus and when with epidemic typhus; both forms were present and both were referred to as Mexican typhus. For several years the murine typhus was misdiagnosed, the cases observed in 1920 in Rome by Carducci would be, according to Pécori, of the cases of murine typhus. In 1929 in Sao Paulo, during an outbreak of *tabardillo*, researchers were able to isolate the bacteria not only from ticks (*Amblyomma* spp.), but also from fleas, urban rats, and small mammals.

In 1923, in the Annual Reports of the Department of Health of Palestine, there was a reference to a mild course of typhus fever, similar to Brill's disease and different from the classic form of typhus. Stuart, in 1924, made the first comprehensive study on typhus in Palestine, and Fletcher and Lesslar in Malaya. In 1925, an outbreak of 200 cases of endemic typhus occurred in Australia. Plazy, Marcandier, and Pirot observed the first Mediterranean cases of murine typhus in sailors on the warships of Toulon (France), Blanc in Morocco, and Nicolle in Tunis (Tunisia). During 1926 and 1932, 135 cases of murine typhus on the warships of Toulon were noted. Lépine in Greece and in Liban observed identical cases, and showed the presence of the microorganism in the brains of infected rats. In 1935–36, Suarez, Palacios, Chavez in Chili, and Sesnic and Giroud in Tunisia identified asymptomatic cases of murine typhus. In the period 1931–46 42 000 cases were reported in the United States. Late reports established the worldwide distribution of endemic typhus. In 1940, Lewthwaite and Savor reiterated the important distinction between the *X. cheopis*-borne murine typhus ('shop typhus') and the chigger-borne scrub typhus ('tsutsugushi' or 'rural typhus').

The designation 'murine' typhus was adopted since the infectious agent was well entrenched in the rat population and its flea throughout the world. About the origin of murine typhus, Traub suggested that the *R. typhi* has always associated with the genus or subgenus *Rattus*, and that, in its ancestral homeland, which was probably in southeast Asia, ectoparasites other than *X. cheopis* were the original intramurid vectors. In contrast, murine typhus existed in a sylvan cycle involving other small mammals (theraphions) and ectoparasites, but spilled over into *Rattus*, which proved to be unusually well adapted to maintaining it and disseminating it

over the world and bringing it in contact with man. The nature of such an aboriginal cycle and its geographic location are yet unrecognized, but the data to date indicate that northern Africa, which was believed to be the origin of *X. cheopis*, is unlikely to be involved.

The Infectious Agent: *Rickettsia typhi*

In the late 1920s and early 1930s, through the efforts of many investigators, the agent of endemic typhus was considered more virulent for the rat than *R. prowazekii*. There was considerable discussion of whether they were variants of the same species or two different species. In 1920, Wolbach and Todd proposed the designation *Dermacentroxenus typhi* for the Mexican variety of typhus. With time *D. typhi* was changed to *R. typhi*, although some rickettsiologists still prefer the designation *R. mooseri* in honor of Herman Mooser. In 1926, Maxcy isolated rickettsia from the blood and noted their antigenic similarity and differences with *R. prowazekii* and *R. rickettsii*. In 1930, Dyer isolated the suggested new 'virus' from fleas collected in Baltimore during an outbreak of three cases of typhus. Mooser recovered the microorganism from brains of rats in a prison of Mexico City, where several inmates had presented typhus fever. The studies of Lepine, Lorandos, Lemiére, Combesco (1934), and Combesco (1935) led to the isolation of bacteria from cats and dogs. *R. typhi* is an obligate intracellular bacterium that infects endothelial cells in mammalian hosts and midgut epithelial cells in the flea host. In 2004, complete genome (1 111 496 bp) analysis of *R. typhi* revealed 877 genes, 40 pseudogenes, and 838 proteins.

Murine Typhus Vectors

In 1926, Kenneth Maxcy, a wise epidemiologist with a clinical background, observed patients and the environments related to their illness, particularly in Alabama, Georgia, North Carolina, and Virginia. He concluded "that the reservoir is rodents, probably rats or mice, from which the disease is occasionally transmitted to man. The parasitic intermediaries which are first suspected are fleas, mites, or possible ticks". Hone in 1927 postulated the same theory, and the vector other than the louse for endemic typhus was reported in Palestine. Maxcy's theory was validated by two different groups.

In 1930, a physician-pharmacist, Dr. J. Lipsky presented fever, headaches, and a rash. His physicians diagnosed typhoid fever, but blood cultures and the Widal reaction were negative, and the Proteus OX19 reaction reached a titer of 1:320. Endemic typhus fever was the discharge diagnosis. On the day of discharge, Dr. Lipsky's female clerk was hospitalized and placed in the same room with the same illness, as was the male clerk 3 weeks ago. Dyer and his associates, Rumreich and Badger, successfully transmit the rickettsial agent to guinea pigs from rats' brains, and fleas, trapped in the basement of Dr. Lipsky's drugstore, Baltimore. They identified the murine reservoir of the rickettsia and incriminated the flea as a vector, showing that the organisms persisted in rat fleas for at least 9 days and were present in feces of infected fleas. The authors found that the flea *X. cheopis* became highly infectious on the fifth or sixth day, remained infectious for 40 days without evidence of ill effect with an inoculum representing 1/128 000 of a flea.

In the same year, Mooser recovered the microorganism from the brains of rats in a prison in Mexico City, where several inmates had presented typhus fever. The attempt of these two groups elucidates the epidemiological cycle of the disease by revealing the reservoir (rat) and the vector (fleas).

Later, Ceder and Dyer noted that the disease was transmitted not by flea's bite, but by inoculation into the flea-bitten part or by skin abrasions with the flea feces or crushed fleas. Mooser and Castenada followed, by cytologic methods, the development and multiplication of the rickettsia of murine typhus in tissues of several species of fleas in epithelial cells of the stomach and in cells of the malpighian tubules. Rickettsiae were not observed in the salivary glands and not in the genitals, thus the fleas were considered inefficient vectors of typhus. Lewthwaite in Malaysia confirmed the findings about transmission via contact with crushed fleas or flea feces, which remains infectious for 8 or 9 years (potential for aerosol transmission) and the absence of transovarian infection.

In 1931, Dove and Shelmire raised a serious doubt as to the exclusive role of flea transmission of endemic typhus, following their studies with the tropical rat mite, *Ornithonyssus bacoti*. They demonstrated the transovarial transmission and the passage of disease from guinea pig to guinea pig and to rat via infected mites. Later, Pang noted natural infection with *O. bacoti* in China. The *Polyplax*, louse of rat, was found infected with murine typhus and was able to transmit the disease experimentally. However, this louse did not bite humans and therefore would not be a direct cause of human infection, but may be important in maintaining enzootic infection. On the contrary, *R. typhi* was isolated from the human louse *P. humanus* from patients in India, Mexico, and Ethiopia. Experimentally infected lice did not transmit *R. typhi* to their progeny. In 1930, Castaneda and Zinsser reported that by experimental model the bedbug *Cimex lectularius* can acquire the rickettsiae of 'Mexican typhus fever', but failed to transmit it to another animal. *R. typhi* was isolated from a pool of *Boophilus* ticks collected from bushes in India and from *Hyalomma* ticks collected from cattle in Ethiopia. Some ecological and epidemiological studies indicate that the ticks and trombiculid mites (chiggers) may be of some importance as vectors but they do not challenge seriously the theory that fleas are the principal carriers to man (Table 7).

Transmission by aerosols and contamination with urine or feces of infected rats or cats that contaminated foodstuffs might account for some cases. Also, the transmission of the disease by mouth by animal experiments and the possibility of transmitting the disease from human to rabbits and to guinea pigs was proved. Some native wild rodents were susceptible to infection with *R. typhi*: the woodchuck, *Marmota monax monax*; the meadow mouse, *Microtus pennsylvanicus pennsylvanicus*; the white footed mouse,

Table 7 Arthropods implicated as actual or potential vectors of murine typhus

Arthropod	Distribution
Fleas	
<i>Xenopsylla cheopis</i> (rat flea)	Almost worldwide
<i>Xenopsylla astia</i> (rat flea)	Southern Asia and coastal East Africa
<i>Xenopsylla brasiliensis</i>	Africa, South America, India
<i>Xenopsylla bantorum</i>	Africa (Ethiopian region)
<i>Ctenocephalide felis</i> (cat flea)	Cosmopolitan
<i>Echidnophaga gallinacea</i> (sticktight flea)	Cosmopolitan
<i>Leptopsylla segnis</i> (mouse flea)	Cosmopolitan
<i>Monopsyllus nesus</i> (murine flea)	Northern Asia
<i>Nosopsylla fasciatus</i> (ceratophyllid flea)	Cosmopolitan
<i>Pulex irritans</i> (human flea)	Cosmopolitan
Lice	
<i>Hoplopleura oenomydis</i>	Cosmopolitan
<i>Pediculus humanus</i>	Almost worldwide
<i>Polyplax spinulosa</i>	Cosmopolitan
Mites	
<i>Echinolelaps echidninus</i>	Almost worldwide
<i>Ascoschoengastia dica</i>	Asia
<i>Ornithonyssus bacoti</i>	Almost worldwide

Peromyscus leucopus neborascensis; the house mouse, *Mus musculus*; and the *spermophiles*, genus *Citillus*. But, the most important components of the murine typhus life cycle are commensal rats of the subgenus *Rattus*, such as *R. rattus* and *R. norvegicus*, and their fleas, in particular the oriental rat flea *X. cheopis*.

Diagnosis and Treatment: Historical Aspects

Diagnosis: The first test for diagnosis of murine typhus was the Weil–Felix test. Weigl reported a more sensitive and specific serological test using suspensions of rickettsia of European typhus and murine typhus grown in the intestine of lice. Today, indirect immunofluorescence assay is the reference method for serodiagnosis of rickettsia in most laboratories, and Western blotting assay associated with the cross-adsorption technique to eliminate the false-positive results through cross reactions between bacteria sharing common antigens, such as *Legionella* and *Proteus* OX-19. A diagnosis of murine typhus can be confirmed by immunohistological demonstration of *R. typhi* in tissues, by polymerase chain reaction (PCR) amplification from blood and by cell culture system.

Treatment: Since 1950, chloramphenicol is the treatment for murine typhus. In the first study, the authors noted that the temperature reached normal levels within 3 days after beginning the therapy. The current recommendation is administration of 100 mg of doxycycline orally twice daily for 2 to 3 days after defervescence, when tetracycline is contraindicated, chloramphenicol is an alternative treatment.

Vaccine: A vaccine for typhus more unique than Weigl's was developed by Blanc and Baltazar using 'attenuated' *R. typhi*-infected fleas' feces with ox bile/saline diluent, in the Institut Pasteur, Casablanca. A later study of this vaccine in volunteers showed that protection against epidemic typhus occurred only when the flea feces in the vaccine was viable and caused a mild murine typhus infection with serological conversion after vaccination. No effective vaccine is available for murine typhus.

Prevention: Prevention is directed primarily toward the control of flea vectors and potential flea hosts. In 1952, a decline in cases of murine typhus in the United States was reported after DDT dusting campaigns. The rate of infection remained low and no human cases occurred in the area for at least 3 years after cessation of the dusting operations. The recent recommendations are rat trapping and application of rodenticides and dusting harborages with carbaryl or permethrin for flea control.

Rocky Mountain Spotted Fever

RMSF caused by *R. rickettsii* is transmitted by the bite of infected ticks. RMSF has not occurred in epidemic proportions, but causes the most severe clinical manifestations of any rickettsioses in early studies with the virulence to kill before the introduction of effective therapies, 10% of children and 30% of adults (Table 3). Currently, it is not so deadly and has a death rate comparable to that of Mediterranean spotted fever (MSF). The average annual RMSF incidence in the United States during 1997–2002 was 2.2 cases per million persons. The disease also occurs in Central and South America, where it is currently largely unrecognized and possibly misdiagnosed as dengue or other febrile exanthems; hence RMSF has been described as a 'wolf in sheep's clothing' and 'the great imitator'.

Around 1 week following the bite of an infected tick, symptoms of illness begins with fever, chills, myalgia, and headache. During the next few days, these symptoms continue and may be accompanied by anorexia, nausea, vomiting, abdominal pain,

diarrhea, photophobia, and cough. The fever is typically high and associated with a severe frontal headache. Rash, considered as the hallmark feature of RMSF, appears on day 3 of fever as small, pink, blanching macules, typically on the wrists, ankles, and forearms, which evolve into maculopapules. Within 24 h, it spreads centrally to involve the legs, buttocks, arms, axillae, trunk, neck, and face. The entire body may be involved, including the mucous membranes of the palate and pharynx. Characteristic of the rash is petechial lesions, the distribution that includes the palms and soles and occurs in only 36–82% of patients. In some severe cases, petechiae may coalesce to form large ecchymoses. Severe manifestations may include pulmonary edema and hemorrhage, cerebral edema, myocarditis, renal failure, disseminated intravascular coagulopathy, and gangrene. Three factors were independent predictors of failure by the physician to initiate therapy the first time a patient was seen: absence of a rash, presentation between 1 August and 30 April, and presentation within the first 3 days of illness. In untreated patients who survive their illness, the natural course of the fever terminates after 2–3 weeks.

Historical Aspects of Rocky Mountain Spotted Fever Disease

It is not known how long *R. rickettsii* has been indigenous to the Western Hemisphere, a reflection of the 500 years or so since the first explorers, slaves, and immigrants inhabited what is now the United States, Canada, Mexico, and Central and South America. According to the US Public Health Service, the earliest account of RMSF dates to 1873 (Table 8). Major W. W. Wood, who collected descriptions of cases from eight Idaho physicians, apparently first recorded the disease in 1896. Edward Maxey published the first report in the medical literature of a case in the Snake River Valley of Idaho in 1899 and he gave a vivid description of the disease known locally as the 'blight on the Bitterroot' or 'black measles'. Its severe dark rash and folk wisdom of the day suggested that infection occurred from drinking the melted snow water that gushed out of Lo Lo Canyon during spring runoff, the notorious site of the infection after Michie and Persons.

In 1902, Wilson and Chowning, both from the University of Minnesota, began a significant epidemiological study. Their valid observations included the first description of severe RMSF, findings from eight autopsies, and geographic distribution on the western side of the Bitterroot River. They correctly concluded that 'spotted fever' was a disease of the capillary circulation caused by a noncultivable infectious agent with a wild reservoir with no evidence of transmission of the disease from person to person or by means of a common water or food supply. With Ricketts' findings of 1906, RMSF became a true disease, not a syndrome. From 1904 to 1913, 96 (63%) of 153 patients died of RMSF in Montana.

Clinically and epidemiologically compatible cases of RMSF were described from New York State as early as 1912; however, the first clinically recognized, laboratory-confirmed case, east of the Rocky Mountains, was documented in an Indiana child in 1925. In 1931, Badger described cases in Delaware, Maryland, North Carolina, Pennsylvania, Virginia, and Washington, establishing the widespread distribution of RMSF in the United States. In 1929 in Sao Paulo, the physicians diagnosed several patients with a febrile exanthematous disease, named 'Sao Paulo exanthematic typhus' or 'Brazilian spotted fever' with a high fatality rate (70%), identifying in ticks (*Amblyomma* spp.) and small mammals a rickettsia similar to the RMSF agent. Recently, contemporary diagnostic methods have permitted the retrospective confirmation of fatal case of spotted fever in a Maryland patient that occurred in 1901. During the next several decades, RMSF was confirmed in Columbia (*Toba petechial fever*), Mexico (*Fiebre de Coix* and *Fiebre manchada*), Canada, Panama, Costa Rica, and Argentina.

The Infectious Agent: *Rickettsia rickettsii*

At the beginning of 1900, research of infectious agent was very difficult because the techniques of visualization of bacteria were imperfect. Sometimes, certain works were false tracks like those of Wilson and Chowning (1904) of Fricks, and Noguchi later (1916), which attribute to the parasite *Pyroplasma hominis* identified in the hypochromic and sledged red cells of an afflicted patient

Table 8 Milestones of Rocky Mountain spotted fever

and in Columbian ground squirrels an etiological role of RMSF. In 1904, Stiles and Craig intensively studied the blood and tissues of spotted fever patients and both showed the absence of protozoan parasites.

The first experimental transmission of infection from the blood of patients to guinea pigs and monkeys was carried out by Ricketts in 1906. The maintenance of the agent via serial animal passages alternating between monkeys and guinea pigs was suggested in his laboratory. Ricketts found that the infectious agent was retained by a small Berkefeld filter, was unable to grow in bacteriologic media, and the guinea pigs could also be infected with serum or washed cells. Later, he described “small spherical, ovoid and diplococcoid forms” in the blood of guinea pigs and monkeys infected with RMSF that seemed to be bacteria and “no so frequently in the blood of men”. By using Giemsa stain, he saw “two somewhat lanceolate chromatin staining bodies, separated by a slight amount of eosin-staining substance”. He wrote, “I have devised no formal name for the organism discussed, but it may be referred to tentatively as the bacillus of Rocky Mountain spotted fever”. It is difficult to recognize *rickettsiae* based on this description. In his carefully prepared laboratory notes, Ricketts made drawings of his parasite. Wolbach was the first to demonstrate *R. rickettsii* in human tissues by using a modified Giemsa stain. He felt that the bodies, when present in the circulating blood, were only within phagocytic cells. In this point of identification of the parasite, Wolbach compared one of Ricketts’ original preparations with those of his own obtained from eggs of infected ticks. He felt that “while Ricketts may have encountered the true parasite of the disease in ticks, he was led hopelessly astray by the occurrence of bacteria in his infected as well as noninfected ticks”.

In the middle of 1916, Wolbach described the morphology of an intracellular bacteria that he called “a wholly new kind of micro-organism”, a Gram-negative bacterium measuring from 0.2 to 0.5 μ m, and has the capacity to infect and replicate in the cytosol and occasionally in the nucleus of vertebrate and invertebrate cells. This was probably the first description of *Rickettsia*. Later, he reported the experimental infection of primates and the post-mortem findings of five cases of RMSF. His meticulous and detailed descriptions of rickettsiae in the tissues of patients with fatal RMSF established the foundation for the current understanding of the pathogenesis of this disease. The similarity of the agent of typhus and tsutsugamushi fever was remarkable as noted by Wolbach. In 1933, Harris showed rickettsiae in the skin of a patient who contracted RMSF in Tennessee. Wolbach named it *Demacentoxenus rickettsii*, the genus name after its vector ticks and the species name after Howard Ricketts. In 1922, Brumpt proposed the name *R. rickettsii* and Bengston in Bergey’s ‘Manual of Determinative Bacteriology’ calls it ‘*Rickettsia rickettsii* (Wolbach)’. The complete genome sequence has not been fully characterized, but contains 1 257 710 bp with an estimated 1365–2849 open reading frames (ORFs) and contains considerable inactivated genetic material in the process of spontaneous degeneration.

Tick Vector

The most brilliant discoveries of the century, quite on par with the great findings of Robert Koch, were the first demonstration of arthropod biological transmission of any disease. The possibility that wood ticks (genus *Dermacentor*) were responsible for transmitting the infection was suggested by an Idaho physician, when a tick was found in the genitals of one of the fever victims. Wilson and Chowning made a crucial association between the discovery of the agent of Texas Fever (*Babesia bigemina*) carried by the cattle tick *Boophilus annulatus* and RMSF. Their acclaimed hypothesis of transmission by tick bite was later rejected when the acknowledged experts – Stiles, Ashburn, and Graig – did not find any protozoa in the patient’s blood.

In 1905, McCalla, an Idaho physician, in association with Brereton, placed a tick obtained from the chest of a man who was very ill with spotted fever on the arm of another patient, with the full consent of the participants. The tick remained on the second patient for 48 h and then placed on the leg of a woman, where it remained for at least 10 h. The incubation periods were 9 and 3 days, respectively. McCalla did not publish his finding. Ricketts, during his investigation of RMSF in western Montana, demonstrated that *Dermacentor andersoni* was the principal vector and showed the transovarial transmission, confirmed independently by Walter W. King. Microscopically, Ricketts found the peculiar microorganisms in salivary glands, alimentary sac, and ovaries of infected females as well as in eggs. In collaboration with King, Ricketts showed the ability of a female tick to acquire the infection by feeding on experimentally infected guinea pigs and to subsequently transmit the illness by feeding on another guinea pig. In 1907, Ricketts had shown that Columbian ground squirrels, chipmunks, and woodchucks were susceptible to *R. rickettsii*. Later, Wolbach concluded that there was no cellular reaction in the tick’s tissues for the presence of the parasites, ‘even when presented in enormous numbers’. Other rarely recognized routes of transmission of *R. rickettsii* include blood transfusion and inoculation of rickettsiae through mucous membranes.

Later, *R. rickettsii* was isolated from other ticks like *Dermacentor variabilis* (Figure 4), *Rhipicephalus sanguineus* (Figure 5) and *Amblyomma cajenense*. Burgdorfer (1963) showed 100% transovarial development of rickettsiae through four additional tick generations and filial infection rates in the seventh generation, but the low proportion of infected ticks in nature was explained by negative effect. Transstadial and transovarial transmission of rickettsiae in tick hosts is central to the maintenance of *R. rickettsii* in nature, the same for the horizontal transmission among tick-feeding animals and vertebrates host.

Over many years, extensive research was carried out to find the reservoir of this disease. *R. rickettsii* was first isolated from small mammals such as a meadow vole (*M. pennsylvanicus*) trapped near Alexandria in 1954 by Gould and Miesse. A decade later, it was isolated from eight other mammalian species, including a pine vole (*Pitymys pinetorum*), white-footed mouse (*P. leucopus*), a cotton rat (*Sigmodon hispidus*), cottontail rabbits (*Sylvilagus floridanus*), an opossum (*Didelphis marsupialis virginiana*), chipmunks (*Eutamias amoenus*), a snowshoe hare (*Lepus americanus*), and golden-mantled ground squirrels (*Spermophilus lateralis tesorum*). The significance of birds as reservoir hosts for *R. rickettsii* remains unproven. The rather limited list of animals from which *R. rickettsii* has been isolated, compared to the extensive list of seropositive animals, is not really surprising when one considers the transient level of rickettsemia in animals.

Diagnosis and Treatment: Historical Aspects

Diagnosis: For the first time a definitive, objective laboratory method for the diagnosis of RMSF was established after Rickett's discovery in 1907, named 'infection test'. The macroscopic changes in infected guinea pigs yielded a distinctive criterion for the diagnosis of the infection. Later, Ricketts developed an agglutination test using infected ticks, but the Weil–Felix test resides as the most widely used confirmatory procedure. In 1948, the test was completed by the complement fixation test, a specific reaction for the spotted fever strain of rickettsiae. Actually, a diagnosis by serology, by PCR assays, immunohistochemistry, or by the isolation of rickettsiae in cell culture was performed.

Prevention: In 1913, Fricks implemented a program for the Public health Service focused on controlling the tick vector in the Bitterroot Valley. In 1946, Smith showed that spraying an area with DDT or other insecticides was ineffective because of the huge territory and the difficulty in getting under low vegetations. Control of infection in nature is not feasible. The best protection to an individual lies in preventing the attachment of a tick to the skin or in removing it before the rickettsias have become 'activated'.

Vaccination: In 1924, Spencer and Parker developed a vaccine for RMSF from infected tick's intestine. In 1938, they showed that during the period of several years in western Montana there were 38 deaths in 50 nonvaccinated adults (76% fatality rate) and only three deaths in 59 vaccinated persons (9% fatality rate). This vaccine not only gives effective protection, but also produces many local and occasionally severe systemic reactions. It is not certain that vaccines against RMSF developed in 1973 by DuPont and in 1983 by Clement do better. At present, no licensed vaccine exists for RMSF.

Serotherapy: In 1908, Ricketts demonstrated passive serum prophylaxis of experimental disease in guinea pigs, but of nine human patients treated with hyper immune horse serum, six died. Later in 1943, the therapeutic use of an immune rabbit's serum as therapeutic doses administered before the third day of the appearance of the rash diminished mortality around 19%; the initiation after the third day of the rash did not alter the ultimate prognosis, it only reduced the toxemic symptoms. The development of antibiotics relegated serum therapy to use only in extremely toxemic patients or in those who have contraindication to chemotherapeutic agents.

Therapy: The goal of chemotherapy was to develop a rickettsiocidal drug. In 1949, Harrel suggested treatment with 'heavy metals' (arsenic and mercury) and with a solution of neoarsphenamine. After discovery of contraindication of sulfonamides, the researcher

proposed the use of PABA as it showed an inhibitory effect on the growth of rickettsiae *in vivo*, but in practice a very large amount of the drug was required. After chloramphenicol discovery, a series of 37 patients with RMSF were successfully treated showing an average on the sixth day of illness, without fatalities. In certain patients with profound toxic syndrome, chloramphenicol with steroids suggested a significant antitoxemic effect. The isolation of viable rickettsiae several years after active infection from RMSF confirmed that the mode of action of this antibiotic is suppressive rather than killing.

In 1949, Harrel reported the first results of aureomycin treatment, highly effective in chick embryos and in guinea pigs, but having a rickettsiostatic effect. After the introduction of broad-spectrum antibiotics in 1948, the incidence of RMSF in the United States dropped to about 250 cases per year (from 500), with only about 24 deaths. In 2007, the recommended therapy for RMSF is doxycycline in a dosage of 100 mg twice daily for adults for 7 days and is continued for 2 days after the patient has become afebrile. Glucocorticoids are sometimes given to severely ill patients, but no documentation of efficacy has occurred. Moreover, they are not recommended, although in experimentally infected dogs treated simultaneously with doxycycline, no detrimental effects of prednisolone were noted.

Mediterranean Spotted Fever

Rickettsia conorii, the causative agent of MSF is transmitted to humans by tick bite, particularly by *Rh. sanguineus* ticks. MSF is endemic in the Mediterranean area, including northern Africa and southern Europe, but new cases were reported sporadically in central Europe, Central and South Africa, and India. The role of MSF in history is unknown because the disease has a moderate severity, but it plays an important role as a public health treat. In 2002, in Italy, the national incidence rate is 1.6 cases per 100 000 persons (but, in Sicily 10 cases per 100 000 persons); in Portugal between 1989 and 2003, the annual incidence was 8.9/100 000 inhabitants; and in Spain as well as in Marseilles between 1983 and 1985, the estimated incidence was 23–45 cases per 100 000 persons.

The incubation period from the time of infection to the onset is 6 days. Often, patients present abrupt fever, flu-like symptoms (headache, chills, arthromyalgias), and a *tache noire* at the tick-bitten site. The *tache noire*, the hallmark of the disease, is an inflamed red papule, the center of which becomes necrotic and black, indolent, and usually localized on the trunk and the legs and arms; in infants it is often on the scalp. It is present in the majority of cases; however, in some patients it cannot be found unlike clinics, in 14–28% cases. On the seventh day of the fever, a generalized maculopapular rash erupts first on the extremities and then on the trunk, often involves the palms and soles, and to a lesser extent the face. Other common clinical manifestations were myalgia (73%), headache (69%), conjunctivitis (32%), hepatomegaly (44%), and splenomegaly (19%). Severe forms of the disease have been reported in 6% of patients, especially in adults with one of the following conditions: diabetes, cardiac disease, chronic alcoholism, glucose-6-phosphate dehydrogenase deficiency, end-stage kidney disease. The mortality rate may reach 2.5% among diagnosed cases. In 1997, in Beja, a southern Portuguese district, the case fatality rate of MSF was 32.3% in hospitalized patients, explicated by the authors by the differences in virulence strains.

Historical Aspects of Mediterranean Spotted Fever Disease

It is evident the first cases of MSF were observed before the first description by Conor and Brush of the Pasteur Institute in Tunis in 1910. The authors described seven cases of spotted fever; they differentiated the disease from epidemic typhus and other eruptive fevers and compared with RMSF (Table 9). Advised by Charles Nicolle, they called the Tunisian spotted fever “*fièvre boutonneuse de Tunisie*”. They made the first experimental infection to chimpanzee (cured of typhus since 45 days). After 10 days of fever, the chimpanzee died. In the same year, Conor and Hayat described the clinical features of other four clinical cases (abrupt onset, high fever, headache, chills, arthromyalgias, and conjunctivitis). The exanthema was papular rather than macular; they named it ‘*bouton*’ and it often turned red-purple in color, involving the palms and soles. The duration of illness was 12–15 days, without fatality cases.

2005 Subspecies of <i>R. conorii</i> based on MLST	Zhu et al.

During the same time, several cases with atypical generalized rash, called 'Marseilles' fever', was reported in the South France. Later, not only sporadic cases, but small endemic cases of spotted fever in the warm months were mentioned in this region. In 1920, in Italy, Carducci reported 16 cases of spotted fever collected during the last 10 years and distinguished two different diseases by clinical and epidemiological criteria: remittent fever and spotted fever, named after "*Febbre eruttiva, forma speciale descritta dal Pr. Carducci*". In 1925, Jean Pièri and Brugeas described a small lesion '*tache noire*', an eschar of inoculation, the hallmark of diseases. In 1928, Roche, a physician of Sorgues, South of France reported, "During 31 years of my professional work, I carried each year, some clinical cases of one mysterious disease to which I was embarrassed to give a name". The physician named it "*exanthème infectieux épidémique, maladies exanthématique, fièvre exanthématique du littoral, and exanthème infectieux méditerranéen*".

In 1925–27, on the Academy of Medicine, Olmer gave an excellent clinical description of the disease and projected new experimental researches on the guinea pigs and monkey for differentiation of epidemic, endemic typhus, and Brill's disease. Boinet and Pieri reported an epidemiological study of disease and insisted that the disease was not very contagious to human, benign, and very different of typhus. Two opposite opinions were projected: Jean Olmer classified this disease in the same group with the typhus. He wrote about several form of typhus: severe winter typhus (epidemic typhus) and benign summer typhus, which consisted of Brill's disease and Marseilles' fever. Several histological studies of MSF between 1932 and 1935 on the skin biopsies showed that *R. conorii* caused vasculitis and was responsible for the clinical anomalies.

The spotted fever disease was clinically described in India by Megaw (1921), who named it Indian tick typhus rickettsia (ITTR); in (1946) Israeli spotted fever rickettsia (ISFR); and in Astrachan, a region of Russia located on the shores of the Caspia Sea (1972), Astrachan spotted fever rickettsia (AFR). Later subspecies of the etiological agent *R. conorii* was isolated from human samples of these diseases.

The Infectious Agent: *Rickettsia conorii*

In 1927, Netter supposed that the agent of spotted fever of Marseille was the same organism associated with Brill's disease, only that it lost some virulence factors by the phenomenon of mutation. In 1932, Blanc and Caminopetros characterized some small bacteria, which seemed probably *Rickettsiae* on the ticks' organ smears using Giemsa staining, and showed that the infectious agent crossed through the filters Chamberland L2 and L3 and remained infectious after centrifugation for humans. P. Durand, Kuszynski, and Hohenadel showed the same results from the skin biopsies of MSF patients.

Brumpt described the infectious agent in tick samples and gave the name *R. conorii* in honor of the work of Conor (Figure 6). *R. conorii* is transmitted by biting, through tick's feces, or by projection of the liquid contents of the ticks on the mucous membrane conjunctivae. The transmission by ingestion as well as the possibility of infection through respiration of environmental pollutants containing Rickettsiae from ticks feces was already noted.

In 1978, Philip by using mouse serotyping demonstrated that Malish, Moroccan, and Kenyan *R. conorii* isolates were closely related antigenically to ITTR and that they belonged to a single serotype. Later, it was demonstrated that AFR differed from both ISFR and *R. conorii* in terms of SDS-PAGE mobility, PFGE profiles, and PCR RFLP, but using a combination of genotypic criteria, the differences were too faint to classify as new species. Among the 39 isolates or tick amplicons studied recently, four multilocus sequence typing (MLST) genotypes were identified; furthermore, they were also classified into four types using multi-spacer typing (MST) genotyping as well as mouse serotyping. Then, four subspecies were reported: *R. conorii* subspecies *conorii* (type strain Malish, ATCC VR-613, formerly MSF), *R. conorii* subspecies *indica* (type strain ATCC VR-597, formerly ITTR), *R. conorii* subspecies *caspia* (type strain A-167, formerly, Astrakhan fever rickettsia), and *R. conorii* subspecies *israelensis* (type strain ISTT CDC1, formerly ISFR). Complete genome sequence determined the 1 268 755 nt of *R. conorii conorii*, containing 1374 ORFs.

Figure 6 *Rickettsia conorii* detected in hemolymph of infected *Rhipicephalus sanguineus* adult ticks by using Gimenez staining.

Vectors History

Several years after the description of the first case by Conor, the researchers tried to identify the vector of disease. Netter and Olmer proposed a red Japanese mite, *Thrombidium akamushi*. After the discovery of 'tache noire', an eschar of inoculation of an infectious agent, all researchers believed in the existence of a vector for the disease. Olmer (1928) thought that the vector of the disease was the brown dog tick, a hypothesis confirmed by P. Durand and E. Conseil, who inoculated to humans the crushed infected *Rh. sanguineus* ticks; the patients contracted MSF (Figure 7). In 1932, it was shown that the different stages of ticks and over winter unfed males and females could act as vectors of MSF. It was also shown that when eggs or larvae obtained from infected *Rh. sanguineus* females were crushed and used to inoculate humans, the patients contracted MSF. Later, the transtadial passage and transovarial transfer to at least some eggs in the next generation were demonstrated. Ranque supposed that the *Rh. sanguineus* retained the *R. conorii* for at least five or six generations. The reproduction and maintenance of *R. conorii* in tick populations may be related largely to the environment of the tick than of the host. However, the transovarial transmission rate, or the filial infection rate, was not proved yet. Later, a negative effect of *R. conorii* on *Rh. sanguineus* ticks was shown in experimentally infected ticks, which may explain the low prevalence of infected ticks in nature.

No animal reservoir of *R. conorii* has been definitely identified, but A. Raybaud (1929) accused the rabbits, hares, weasels, and fox; Godlewski thought that the herds transhumant that return from the Alps could import in the suburbs of Avignon their ticks and spotted fever; Brumpt suspected the dog, but also various wild animals, cats, rabbits, the rodents, or insectivorous; and Plazy, Marcon, and Carboni suspected the rats. In 1930, Durand infected two 6-week-old puppies with an emulsion of *Rh. sanguineus* ticks collected in Tunis, and no clinical symptoms were observed. The administration of blood collected from these puppies (10 days postinfection) caused typical symptoms of MSF in human subjects. Laboratory experiments found that the dog, rabbit, guinea pig, and rat were not susceptible to infection. Swiss mice, Hartley guinea pigs, spermophile (*Citellus citellus*), and the chimpanzee are susceptible. In 1932, the European rabbit *Oryctolagus cuniculus* was considered a possible reservoir. In 1940, Violle and Joyeux isolated *R. conorii* by inoculation of wild rabbit's blood, brain suspension, and crashed ticks into guinea pigs. Furthermore, in 1952, myxomatosis destroyed almost all the rabbits in southern France. Immediately thereafter, there was a spectacular drop in the incidence of MSF, and the reappearance of wild rabbits several years later was followed by an increased incidence of MSF. The role of small rodents such as *Pitymys duodecimcostatus*, living in rabbit's burrows, was suspected to be involved in the life cycle of *R. conorii*; however, this was never confirmed. Later, *R. conorii* was isolated from rats and mice by inoculation of spleen and brain material into guinea pigs. Each of these rodents is a characteristic host of immature *Haemaphysalis leachi* and *Rhipicephalus simus* ticks in Kenya. Recently, some ticks collected on a hedgehog were tested positive for *R. conorii*, but their role in transmission is not proved yet.

Diagnosis and Treatment: Historical Aspects

Diagnosis: The first keys for diagnosis were the clinical presentation with generalized maculopapular rash that often involves the palms and soles and the black eschar 'tache noire'. The diagnosis may be established by immunofluorescent detection, latex agglutination, enzyme immunoassay, Western blot, complement fixation, immunohistologic demonstration of *R. conorii* in skin biopsy, isolation in shell vial cell culture, and PCR can be applied to blood or skin biopsy. Recently, diagnostic criteria have been proposed to help physicians in diagnostic MSF and other rickettsial diseases.

Treatment: In 1949, Janbon and in 1950, Fouquet and Morin investigated chloramphenicol as treatment for MSF. Actually, the treatment of choice for MSF is 200 mg of doxycycline, a single dose, although for severe forms, it should be administered until the patient becomes afebrile.

Figure 7 *Amblyomma variegatum* (female left) and male (right) adults, nonengorged implicated in the transmission of *Rickettsia africae*.

African Tick Bite Fever

African tick bite fever (ATBF) is due to *Rickettsia africae* transmitted by *Amblyomma* ticks in rural sub-Saharan Africa and the French West Indies. Some reports indicate that ATBF pose a significant problem to local populations. During Zimbabwean war of independence in the late 1970s, army medical authorities reported several thousand cases of tick typhus. Both European and African soldiers were affected, although the infection rate seemed to be greater among the former. In Zimbabwe, the incidence rates of ATBF was 60–80 cases per 100 000 patients each year in areas where *Amblyomma* tick was endemic. Whereas reports on ATBF in indigenous populations are scarce, the number of reported cases has recently increased in travelers from Europe and elsewhere.

The clinical course typically comprises an abrupt onset of fever, nausea, headache, and neck myalgia beginning 5–10 days after a tick bite. Most patients develop an inoculation eschar at the site of the tick bite and up to 54% of patients have multiple eschars, a pathognomonic clinical sign. A painful regional lymphangitis is common and may be seen in the absence of a franc eschar. A generalized cutaneous rash, sometimes vesicular and usually best seen close to the eschar, is present in 15–46% of the patients. Less frequent clinical signs of ATBF include apthous stomatitis and arthralgia. Complications are rarely seen, but it was reported in one patient presenting long lasting fever, reactive arthritis, subacute cranial or peripheral neuropathy, chronic fatigue, neuropsychiatric symptoms, myocarditis, and there are no other known fatal cases. ATBF should be considered along with malaria and other tropical fevers in the differential diagnosis of all febriles returning from the tropics.

Historical Aspects of African Tick Bite Fever Disease

ATBF is probably a very old disease in sub-Saharan Africa, which for several decades has been confused with the MSF. The first human case was described in 1911 by McNaught in Mozambique and South Africa, and by Sant'Anna and Nutall in Angola and Kenya (Table 10). They named this disease as tick bite fever because it was transmitted by ticks. In 1929, Béros and Belozet suggested that this disease was the same as MSF. During the 1930s, Pijper, a pathologist working in Pretoria, described the distinct epidemiology and the clinical features of ATBF, isolated a causative organism from ticks, and concluded that ATBF was a separate disease from MSF (which at the time was known to be caused by *R. conorii*). Pijper noted that the vector of the disease was cattle ticks; the clinical manifestation was milder, less illness period with few complications, rare cutaneous rash, and no fatality case. However, subsequent experiments by Gear failed to confirm these findings and he reported the infection of *R. conorii*. For the next 52 years, ATBF were erroneously considered as MSF, which was also present in the same geographic areas, and the observed differences in clinical presentation and epidemiology were attributed to different host factors, such as age and risk behavior.

The final advancement came several decades later; in 1992, a 36-year-old woman presented a history of tick bite behind the right ear, high temperature, and a severe headache. The skin at the bite was erythematous and she had regional lymphadenopathy. The bacterium was isolated and molecular tools confirm that it was distinct of MSF's agent. The authors proposed the name ATBF for the disease. Since then, there have been several reports describing the clinical and epidemiologic features of a number of patients with laboratory-confirmed ATBF.

The Infectious Agent: *Rickettsia africae*

In 1930, Pijper isolated for the first time the causative agent of ATBF in guinea pigs and showed the difference with *R. conorii* and *R. rickettsii* by using cross-protection studies. He described the clinical signs of experimentally infected guinea pigs and the difference with other rickettsial infection. Unfortunately, his isolate was lost. Several years later, different strains from South Africa, Kenya, and Northwest Africa were tested by the toxin-neutralization test in mice, serological and cross-protection tests, but have shown no significant differences with *R. conorii*. Extensive experiences with rickettsial agents and their clinical manifestations have led American and Russian specialists to agree in considering *R. conorii* as a single African rickettsial species and MSF as a single clinical entity. The French school still regards this subject differently.

SFG rickettsiae other than *R. conorii* from Africa were reported from *Amblyomma* ticks in Ethiopia and from *Amblyomma hebraeum* in Zimbabwe. These strains were indistinguishable through serological tools, but distinct from *R. conorii*. Finally, in 1992, one rickettsial agent was isolated from a woman presenting a typical ATBF, and shown to be distinct from *R. conorii* but identical with rickettsial strains isolated in *Amblyomma* ticks collected in Etiopia and Zimbabwe. The authors proposed the name *R. africae*, nomenclatures that were made official in 1996. The genome of *R. africae* consists of a circular chromosome of 1.2 Mb.

Table 10 Milestones of African tick bite fever

Discovery: African tick-bite fever: <i>Rickettsia africae</i>	Author
1911 The first human cases	McNaught, Sant'Anna JF
1930 Isolation of <i>R. africae</i> and description of the disease	Pijper
1990 Isolation of <i>R. africae</i>	Kelly
1992 The name of diseases and of bacteria	Kelly and Raoult
1996 Official nomenclatures	Kelly and Raoult
2007 Genome sequence	Raoult D

Tick Vector

Sant'Anna and Nutall described, in 1911, one new disease transmitted by *A. hebraeum* ticks, especially in places frequented by cattle in Mozambique. Later in South Africa, Pijper described tick bite fever as a rural disease occurring in people having contact with cattle tick. He showed that *A. hebraeum*, *Rhipicephalus appendiculatus*, and *Boophilus decoloratus* ticks are able to transmit the infectious agent. In the following years, Rickettsial agent was reported as *R. conorii* from *Amblyomma* ticks. In the light of actual data, these results are amazing; it would be interesting to test by genotyping the old samples for the presence of *R. conorii* or *R. africae*. In 1990, Kelly isolated rickettsial strains from *A. hebraeum* ticks collected in Zimbabwe and demonstrated the transovarial and transovarial transmission of *R. africae* in this tick. Thus, *A. hebraeum* in southern Africa and *A. variegatum* in West, Central, and East Africa and in the Caribbean are the vectors of ATBF and in the same time the reservoir of *R. africae*.

Diagnosis and Treatment

Diagnosis: In addition to the archaic and poorly specific Weil–Felix test, which continues to be used as a first-line test in many countries, immunofluorescence assay is the most widely used microbiological test. More specific serological tests for ATBF include multiple antigen immunofluorescence assay, Western blotting, and crossadsorption assay. Isolation of *R. africae* from cell cultures and antigen detection by immunohistochemistry or PCR are available to such specialized laboratories, and should be attempted in unusual or complicated cases.

Treatment: The treatment described by Sant'Anna in 1911 for a new tick bite disease with a little effect was the aspirine and alkalies given internally, besides purgatives, and an ointment of potassium iodide and iodine applied externally. Currently, then, doxycycline 100 mg twice daily for 7 days or until 48 h after defervescence can be recommended in severe cases of ATBF. Fluoroquinolones may be also beneficial. Patients with mild symptoms may not require any treatment at all.

Other Rickettsioses

A bacterial species reflects the sum of the biological information on a group of closely related strains isolated in pure culture. It is currently considered that strains with more than 3% divergence belong to different species. Specific rules for recognizing, naming, and classifying species have been established, which avoid redundant descriptions and the use of the same name for more than one species. Several prerequisites are necessary before a new bacterial species is validated. The bacteria should be isolated in pure culture and the description should be based on a minimum of five isolates for environmental bacteria. The new species should exhibit both genomic and phenotypic discriminative characteristics. A type strain should be identified for each new species and available to the scientific community through two independent official culture collections. Finally, the new bacterial name should appear in the approved lists of bacterial names.

With the advent of molecular classification, many of the currently accepted *Rickettsia* species were identified genetically before they were cultured in the laboratory. As is the case with other bacteria, *Rickettsia* could be given Candidatus status if they fulfill the genomic criteria but have to be cultured. A subspecies is the lowest taxonomic rank that is recognized officially. It contains closely related strains that have distinct phenotypic traits, but do not meet the genomic criteria required for classification as a distinct species. The official validation of a subspecies is comparable to that of species.

The rickettsiae designated as human pathogens have been isolated in cell culture and/or have been detected by molecular methods from blood or tissues of patients presenting illnesses clinically compatible with spotted fever rickettsioses and seroconversion using reference laboratory methods. We have briefly described, in [Table 2](#), the first clinical description, rickettsia isolation in cell culture, vector discovery, and other historical aspects of human pathogens *R. sibirica sibirica* (Siberian tick typhus), *R. acari* (Rickettsialpox), *R. australis* (Queensland tick typhus), *R. slovaca* (Tick-borne lymphadenopathy (TIBOLA), Dermacentor-borne necrosis–erythema–lymphadenopathy (DEBONEL)), *R. japonica* (Japanese or oriental spotted fever), *R. heilongjiangensis* (Chinese spotted fever or Far-Eastern tick-borne rickettsiosis), *R. honei* (Flinders Island spotted fever), *R. sibirica mongolitimonae* (Lymphangitis-associated rickettsiosis), *R. felis* (Flea-borne spotted fever), *R. aeschlimannii*, *R. massiliae*, *R. parkeri*, *R. raoultii*, *Candidatus Rickettsia marmionii*, *Candidatus Rickettsia kellyi*, and *Candidatus Rickettsia monacensis*.

Many other rickettsiae, not rewarding the pathogenicity criteria, have been identified in ticks and other biological niches. The list of rickettsial species of possible or undetermined pathogenicity in humans is provided in [Table 11](#) with validated species: *R. asiatica*, *R. canadensis*, *R. montanensis*, *R. peacockii*, *R. rhipicephali*, *R. tamurae*, and the rickettsiae classified as *Candidatus* species.

Conclusion

During more than a century of microbiological studies of rickettsial infections, our knowledge has fabulously progressed through description of clinical features, discovery of infectious agents and their arthropod vectors, and understanding mechanism of transmission, several pathogenic mechanisms of tissue injury, the modern diagnostic tools and a optimal treatment. These arthropod-associated intracellular bacteria are now being recognized in all parts of world. Rickettsial diseases retain several of its mysteries, and continue to provide countless exciting opportunities for rickettsiologists and rickettsiology. High levels of awareness,

Unusual Infectious Agents

Shaun Heaphy, University Road, Leicester, United Kingdom

Introduction

Infections are caused by infectious biological agents spreading between organisms, see Fig. 1. Infections may be harmless, beneficial or cause disease. Cell-based agents can be defined as having their genetic information and ribosomes bounded by a lipid membrane. Cellular agents are either Archaea, Bacteria or Eukaryote, not all are infectious but some of each group are. These would not be described as unusual infectious agents. I will, however, make several observations about them that I think are unusual. Firstly, the Archaea that infect human beings are not yet clearly associated with the development of any disease-why not? This is an observation that may change in the future with the use of enhanced genomic sequencing techniques. Secondly, the process of infection and disease can be complicated. Many infection or disease outcomes are complicated by co-infections, host genetics and environmental factors. Two examples: (1) Epstein Barr virus EBV, infects most humans, sometimes causing disease such as infectious mononucleosis (glandular fever). *Plasmodium falciparum* infection invariably causes malaria. Co-infection with *P. falciparum* and EBV can cause Burkitt's lymphoma. (2) Eukaryotic filarial nematode infections are associated with onchocerciasis or river blindness and lymphatic filariasis or elephantitis. However, much of the inflammatory pathogenesis is probably due to the immune response to an intracellular bacteria of the *Wolbachia* genus infecting the nematode rather than to the nematode itself. Finally some cancer cells are infectious and able to spread the cancer between host organisms, a point I will expand on later.

Virus particles are not cell-based, containing neither ribosomes nor necessarily a lipid membrane. The defining feature of a virus is that the genetic information is bounded by a protein layer called a capsid. A virus has to infect a cell that can provide the energy and molecules necessary for the synthesis of new virus particles. Some viruses are associated with unusual infectious agents called satellites or satellite viruses (Fig. 1). These satellite agents require co-infection with a helper virus to facilitate replication. Satellites can have DNA or RNA genomes, the virusoid subgroup have circular single stranded RNA genomes. Viroids are small replicating RNA molecules that directly infect other cells. Prions and prionoids are infectious proteins. Prionoids are able to spread between cells and prions between cells and organisms. This chapter summarizes our understanding as of early 2018 of these various agents.

Sub-Viral Agents: Dependoviruses, Satellites, Satellite-Like Nucleic Acids, Virusoids and Virus-Dependent Nucleic Acids

There is a seeming continuum of infectious agents from viruses through to replicating nucleic acids that all require co-infection with another virus for transmission. Transmission is via a virus-like particle which may contain copies of both the virus and sub-viral genome or just the sub-viral genome (Fig. 1). The virus-like particle may be formed by either the helper virus, the satellite virus or be a chimera of both. The international convention on the taxonomy of viruses or ICTV states that the distinctions between these agents is subtle and not always straightforward. Indeed they were not subject to formal classification in the most recent 2012 classification. It was noted that some satellite agents were also anomalously classified as a virus. For example, virus particles classified in the *Dependovirus* genus and *Deltavirus* genus (discussed later) meet all the definitions of a satellite virus. Thus, the adeno-associated satellite virus AAV, classified as a Dependovirus, require cells to be coinfecting with one of several other viruses for replication such as an adenovirus. The co-infecting helper virus is essential for AAV virus particle formation but does not form part of the virus capsid (Fig. 1A).

Satellites are subviral DNA or RNA agents, double and single stranded, that lack gene functions required for their replication and require co-infection with a helper virus for multiplication. Satellite viruses encode structural proteins that package the satellite genome which is then incorporated into the helper virus particle such as chronic bee-paralysis-associated satellite virus (Fig. 1B), the helper virus is CBPV. Satellite nucleic acids do not encode structural proteins, they may not encode any proteins, the genomes are necessarily incorporated into the helper virus particle, for example, artichoke mottled crinkle virus satellite RNA (Fig. 1C), the helper virus belongs to the Tombusviridae. Some viruses are "defective" and replication requires the presence of a small nucleic acid

Fig. 1 Left hand panel, infectious cells can be bacterial, archaeal, eukaryotic and even cancerous. Prions, viruses and viroids can also be directly infectious. Right hand panel, shows a cell infected with a replication competent virus and viroid (top LH and RH side, respectively). Also shown are various sub-viral agents: A—dependo virus (red) requiring another virus to replicate. B—Satellite virus encoding a structural capsid protein C—satellite nucleic acid not encoding a structural protein dependent upon virus for replication. D—Defective virus requiring a complementing satellite-like nucleic acid. E—Autonomously replicating nucleic acid or satellite requiring a virus for transmission. A satellite virus encodes proteins that package the genome but still require a helper virus. If the satellite virus or nucleic acid has a circular RNA genome it is called a virusoid. See text for details.

~1–1.5 kb in size that rescues or “complements” the defective virus by supplying an essential biochemical function. These small nucleic acids are called “satellite-like nucleic acids.” Examples include RNA associated with members of the *Umbravirus* genus and DNA associated with members of the *Begomovirus* genus (Fig. 1D), which together infect a wide variety of plants. Other nucleic acids are capable of autonomous replication, so strictly speaking are not satellites but they require a helper virus for transmission such as the alphavirus DNAs also transmitted by members of the *Begomovirus* and the *Polyomavirus* associated RNAs, Fig. 1E.

Virusoids have no formal status in the ICTV classification, but the term is often used. They are satellite nucleic acids with a small, ~220–388 circular single stranded RNA genome (Fig. 1B or C). Replication occurs in the cytoplasm. Many examples infecting plants are known such as tobacco ringspot virus satellite RNA and the required helper tobacco ringspot virus. Coinfection of a cell with virus and satellite agent may increase or decrease pathogenicity or have no effect upon it.

Hepatitis D virus, HDV is a well known human satellite virus (Fig. 1B). HDV is also classified as a *Deltavirus* by the ICTV. The essential helper virus is Hepatitis B, HBV. Coinfections with HDV and HBV are usually resolved quickly. Superinfection, where an HBV-infected individual is then also infected with HDV, often leads to a chronic infection associated with a virulent more aggressive form of hepatitis. The genomic circular single stranded RNA genome of HDV is about 1679 nucleotides in size. A ribozyme is active in replication of both the genome and antigenome strands. Replication may resemble the symmetric pathway for viroids described in Fig. 2 and below. The circular antigenome strand made during replication gives rise to a mRNA, which encodes a protein called the delta antigen. A small, S form of this protein is necessary for genome replication. RNA editing, later in infection, results in a large, L form being made and a shift from genome replication to genome packaging. The L form contains a prenylation site which directs the genome to assembling HBV particles. This ensures the HDV genome associated with about 70 copies of the S and L delta antigen is packaged into a HBV like particles, displacing the HBV genome. HDV replication has features that resemble both a viroid (see below) and a satellite virus.

The term “virophage” has been used (but is not generally accepted) to describe subviral agents co-infecting virus infected amoebal cells such as Sputnik virus that infects *Acanthamoeba polyphaga* cells infected with the *Mamavirus*. These agents are currently classified by the ICTV as satellite viruses replicating as shown in 1A or B.

Viroids

Viroids are widely spread infectious agents of many plant species. They were first described in 1971 by T. O. Diener studying an infectious disease of potatoes described some 50 years previously, for which no infectious agent had been identified. Subsequently

Fig. 2 Viroid replication, see text for more details.

more than 30 different types of viroid have been identified infecting a wide range of other crops including tomatoes, avocados, peach, apple, hops and coconuts. They can impose a significant economic burden on the horticultural and agricultural sectors of the economy. Viroids are composed entirely of RNA, being small, ~246–401 nucleotides in size, and forming closed circular, partially base paired rod-like molecules (Fig. 1). The RNA genome encodes no proteins. Viroids are infectious RNA molecules capable of moving from cell to cell and plant to plant. They move between plant cells via the plasmodesmata and within the plant via the phloem system. Unlike satellite agents they do not require the presence of other infectious agents for their spread. They can be spread via seed, pollen, vegetative propagation, contaminated horticultural implements, water and insects. They can interact with host cell proteins causing cellular pathology such as an RNA-activated protein kinase that phosphorylates other plant proteins disrupting protein synthesis. Cell protein expression can also be disrupted by smaller “silencing” siRNAs formed by cleavage of double stranded regions of the viroid genome.

Viroids are divided into two major groups (Fig. 2). The biggest group are the *Pospiviroidae*, type species Potato spindle tuber viroid. These replicate in the nucleus of the cell. The smaller group are the *Avsunviroidae*, type species Avocado sunblotch viroid. These replicate in the chloroplasts of cells. The pospiviroids contain a conserved central region or CCR, the function of this is not clear but it is presumably essential for the replication of this group. The avsunviroids do not contain the CCR, but contain a particular type of ribozyme called a hammerhead. Ribozymes are catalytic RNA molecules; the hammerhead ribozyme cleaves RNA and is essential for the replication of this class of viroid. Viroids of both classes require three catalytic activities for replication; a polymerase, nuclease and ligase (Fig. 2). A cell RNA polymerase class II activity makes the viroid RNA genomes, this enzyme is located in both the cell nucleus and chloroplast. An RNase activity generates genome-sized units from a concatenated genome; pospiviroids use a nuclear RNase III activity, avsunviroids are cleaved by the hammerhead ribozyme activity present in both the positive (+) and negative (–) strands of the genome. Pospiviroids use a nuclear DNA ligase activity and avsunviroids a tRNA ligase activity to ligate and circularize the genomes. Note that the RNA polymerase and DNA ligase enzymes usually function with DNA as a template but are also able to use a viroid RNA template.

The replication of viroid genomes is shown in Fig. 2. By convention the infectious strand is described as positive (+). The + strand genome in blue is copied by RNA polymerase II in a “rolling circle” mechanism resulting in a long strand of RNA in the negative (–) sense having many copies (concatemers) of the genome in red. In the avsunviroidae group the concatemers are self cleaved by the hammerhead ribozyme activity to form monomeric linear negative strands red which are ligated by the tRNA ligase activity to form circular—antisense copies of the genome. These serve as a template for another round of rolling circle replication to form viroid concatemers in the positive sense (blue), which are cleaved by the ribozyme, also active in the + sense genome and ligated by the tRNA ligase activity (blue circles). Because both the negative and positive strands are formed in the same way via a rolling circle this is described as symmetric replication. The pospiviroid group start their replication in exactly the same way as the avsunviroids. The + strand genome is copied by RNA polymerase II in a “rolling circle” mechanism resulting in a long concatenated—sense RNA to form a concatenated + sense RNA, blue. RNA pol II then copies the concatenated—sense RNA to form a concatenated + sense RNA, blue.

These are cleaved to genomic size by RNase III and ligated to form the infectious circular form using DNA ligase. Because the + strand (blue) concatemers and genomes are not formed by rolling circle replication (unlike the – red strand) this is called asymmetric replication (Fig. 2).

The origins of these various subviral particles is not known with any certainty. One theory postulates that they originate from a prebiotic world populated with replicating RNA molecules. These eventually adapted to replicating in cells, the viroids perhaps? The differences in structure and replication between the two viroid groups indicate different evolutionary origins. It has also been proposed that they have evolved from the diverse cellular pool of small RNA molecules that is produced by normal gene expression and RNA transcription. In the case of the other subviral agents, some replication-competent viruses may have lost functionality and became replication-incompetent. Their continued viability then depended upon co-infection with helper viruses. Most satellites share some common sequences with their helper viruses, particularly at the termini of the genome but lack substantial similarity elsewhere. Other agents may have arisen from the cellular pool of viral and cellular nucleic acids. Complementing RNAs and possibly chimera formation between viral genome fragments and other cellular RNAs with subsequent selection for forms able to replicate and transmit may have resulted in the rich (and perhaps confusing) variety of infectious agents described above.

Prions and Prionoids

In the late 1950s a new disease called kuru was identified in the Fore region of New Guinea. It was characterized by a progressive loss of control of nervous function including movement and mental function resulting in death within a year or so of symptoms appearing. It was quickly realized that ritual cannibalism of dead tribal members was responsible for transmitting the disease. Within a few years it was established that kuru was similar to a number of neurological diseases in humans including Creutzfeldt-Jacob disease or CJD, Gurstmann-Sträussler-Scheinker syndrome or GSS and also in animals such as scrapie in sheep. Observation and experiments showed that these diseases could appear sporadically including CJD, or be infectious such as scrapie, CJD, kuru, or be inherited as for GSS and a minority of cases of CJD. More recently other examples of this class of disease including BSE in cows, CWD in mule-deer and elk, FFI and v-CJD in humans have been identified. It has also been recognized that these diseases can be spread iatrogenically, that is, by medical procedures due either to the use of contaminated instruments or the transfer of infected tissue grafts such as cornea, dura mata, blood products and hormones. Together this family of diseases are often called transmissible spongiform encephalopathies.

At first, the transmissible agent was thought to be a virus. It existed as various strains that differed in pathogenic properties. These pathogenic properties were inherited as the strain passed from animal to animal. However, its biological features were very different to any other infectious agent then described. It was extremely resistant to heat, radiation, and other chemical procedures which were known to destroy RNA, DNA, protein and other infectious agents such as bacteria, viruses and viroids. Its resistance to radiation implied that any nucleic acid genome associated with the infectious agent could only be about 60 nucleotides in size. This led to the bold suggestion by J. S Griffith that the infectious agent was a protein, now named a prion. This idea was not immediately accepted because the concept of an infectious protein was new and it was not apparent how an infectious protein could exhibit the strain properties described above. However research by many scientists, especially S. Prusiner, over the following decades proved beyond a reasonable doubt that the the infectious agent comprises a protein made by the host.

The prion was shown to be a form of a cellular (shown as a small superscript^c) protein called PrP^c. PrP^c exists as a protease-sensitive form in normal cells. It is translated into the endoplasmic reticulum and undergoes post-translational chemical modifications and transport to the extracellular face of the outer cytoplasmic membrane where it resides. It can also be endocytosed back into the cell. It is not absolutely essential for cell function because *PrP* gene knockout animals which do not make PrP^c are viable. Importantly these animals cannot be infected with or propagate prions, demonstrating the importance of PrP to infectivity. Although nucleic acids were associated with prions purified from animals, none could be shown to be specifically associated

Fig. 3 Tasmanian devil with transmissible facial tumor.

with the prion. Nor could any specific chemical modification be associated with the prion. This led to the suggestion that the difference between normal cellular PrP^c protein and the prion was in their conformation.

PrP^c is known to fold into a structure which is predominantly alpha-helical one clear difference between many uninfected and infected subjects was the appearance of an amyloid deposit of protein in the brain and other tissues. A smaller N-terminal truncated form of PrP is the major component of this amyloid and in this form is known as PrP^{sc} (the superscript^{sc} is for scrapie). Many proteins are known to form amyloid and amyloids are characterized by having a similar β -sheet folded fibrillary structure. This suggests that PrP can adopt two stable conformations, one predominantly α -helical and one predominantly β -sheet. It is this β -sheet form which is the disease-causing prion and a truncated form of it accumulates as the amyloid PrP^{sc}. It is proposed that PrP^c interacts with the infectious prion and this interaction results in PrP^c changing its conformation from the α -helical form to the infectious β -sheet prion form. Prions thus accumulate exponentially in infected tissues due to the continued misfolding of PrP. This eventually leads to pathogenesis, disease manifestation and the appearance of tissue amyloid protein deposit.

In recent years the prion hypothesis- namely that the infectious agent is a distinctly folded form of the PrP^c protein has been proven beyond reasonable doubt. PrP protein expressed in bacteria in association with a chemically synthesized RNA and lipid is able to form a prion and cause transmissible prion disease in animals in strain specific fashions. PrP is thought to fold in a number of subtle distinct conformations that give rise to different strain characteristics. Whether the lipid and RNA molecule form part of the prion or are just required for its formation is not known.

This understanding of the nature of a prion leads to an explanation for inherited, sporadic and transmissible forms of the disease. Sporadic cases may arise because the conformation of PrP^c can change to the prion form spontaneously. If it does so exponential amplification of the prion leads to disease. This happens only rarely and usually manifests itself in older individuals, perhaps because the ability to prevent prion replication naturally declines with age. In transmitted cases the infectious dose of prions is high enough to overcome any normal resistance to prion amplification. In inherited cases, mutations in the PrP gene manifested in an altered protein structure either increase the rate of prion formation or susceptibility to prion infection from dietary or environmental sources, such that disease is an inevitability.

The development of the prion hypothesis has led to the recognition that it may apply to other proteins. Thus prions involving different conformations of a protein with the dominant prion conformation conferring distinct and transmissible traits has been recognized in yeasts, fungi, and other organisms. Amyloid A, AA, amyloidosis is a transmissible disease in captive cheetahs and other animals and birds and can thus be considered a prion disease. AA amyloidosis occurs in humans but it is not known if it is also infectious.

Many other human diseases are associated with the formation of amyloid deposits containing host proteins. The process is thought to be related to the disease manifestation. Examples include Alzheimer's with two associated amyloids, β -amyloid and tau and Parkinson's associated with α -synuclein amyloid. These diseases are not known to be infectious but there is increasing concern that under some circumstances they may be. For instance α -synuclein amyloid and Parkinson's type symptoms has been shown to be transmissible in a mouse model. β -amyloid associated with Alzheimer's can be transmitted from cell to cell. Evidence of the transmission of the β -amyloid pathology due to childhood neurosurgery or the receipt of growth hormone injections has recently been described, and associated with development of early cerebral amyloid angiopathy but not yet with Alzheimer's.

The term prionoid has been coined to describe cellular proteins able to change from one conformation to an amyloid structure and transmit this change in conformation to other homologous proteins and from cell to cell. It has been suggested that prionoid functions may normally exert another level of control in cell physiology which when aberrant may lead to disease. Thus, a prionoid transmits a change in protein conformation from cell to cell within a host leading to disease. A prion acts in exactly the same way but can additionally be transmitted between hosts.

Infectious Cancer Cells

Cancer in humans is associated with mutations in the genome which disrupt cellular growth control mechanisms leading to uncontrolled cell proliferation and the spread of tumor cells throughout the individual. A cancer is usually derived from one ancestral cell and said to be clonal. It is well established that many cancers of humans and animals are caused by infections. Thus, for instance, cervical cancer is associated with the sexual transmission of some strains of the human papilloma virus. More recently, it has been suggested that the bacterium *Helicobacter pylori* may also be implicated in the development of stomach cancers. The infectious agent results in increased cell growth, genomic mutations and eventually a tumor.

Less well known is that cancer cells themselves can also be infectious. Cases of cancer transmission from mother to baby whilst in the uterus and from organ donor to organ recipient are known to occur. There is also the report of the transmission of a cancer from a patient to a surgeon, following a cut with the operating scalpel. The patient sarcoma was shown to be genetically identical to the tumor on the surgeon's hand, which was removed. Such cases involve the direct transmission of cancer cells from one individual to another when in intimate contact. These cancer cells then manage to avoid the immune system in the newly inoculated and infected individual and go on to establish new tumors.

However, we now know that cancer cells are more commonly transmissible than had been thought. A canine transmissible venereal tumor, CTVT, not usually fatal and spread during coitus, has been estimated to have been established in the dog population for 11,000 years. It is found on five continents and causes growths on the genitals of affected dogs. Also a recently recognized fatal tumor of the face and mouth of the Tasmanian devil, called devil facial tumor disease, or DFTD, is transmitted during eating and fighting behaviors (see Fig. 3). Indications are that DFTD first occurred in a female in the 1990s. A second distinct

form of DFTD also appears to have recently arisen in a male. The fact that infectious cancers have arisen twice in the Tasmanian devil in such a short period of time may indicate that transmissible cancers frequently occur. CIVT and DFTD cancers are being spread by cells transmitted from one individual to another. It has been shown by genome sequencing that all three tumor types are essentially identical to each other that is, derived from three different clonal tumor cells. Genome sequencing shows that these cells have accumulated many mutations which together allow them to avoid the anti-tumor actions of the host immune system. These mutations include down regulation of the MHC cell surface receptors, which presumably prevent the immune system from destroying the cancer cells. In the case of the Tasmanian devil a lack of genetic diversity in the animals may also have facilitated the spread of the tumor.

Even more recently, five different clonal transmissible cancers have been found to spreading in at least 15 marine bivalve populations species such as soft cell clams *Mya arenaria*, the mussel *Mytilus trossulus* and the clam *Cerastoderma edule*. They have collectively been called bivalve transmissible neoplasias, BTN. Cases have been reported in the Pacific and Atlantic. In one case the neoplasia has spread from one species of clam *Venerupis corrugata* to another species of clam *Politatus aureus*. Cancer cells are presumably spreading via the water.

Other metazoan animals and parasites also develop cancers. Parasite infections are often associated with suppression of the host immune system which in turn allows cancer to develop. Recently a fatal case of a histologically unusual tumor in a HIV-1 positive Columbian man living in Medellin was described. He was also infected with the tapeworm *Hymenolepis nana*. His tumor was widely spread, the cells were atypically small and found to be derived from cells of the tapeworm. Further investigation showed that the cancer cells contained mutations commonly associated with development of the disease. It is possible that immunosuppression in this individual allowed *H. nana* growth and genome mutations to occur, which gave rise to the tapeworm tumor which spread to his organs.

Conclusions

Agents responsible for infections are more diverse than is generally realized. Some diseases we don't currently recognize as being transmissible may be under some circumstances. In addition to the widely known bacterial and eukaryotic infectious agents some Archaea are also infectious. I have described a continuum of sub-cellular infectious agents including viruses, defective viruses, virus satellites and viroids. I have referred to strong evidence that some cancer cells including CIVT, DFTD, and BTNs are infectious agents and that some proteins named prions are also infectious such as PrP^{sc} and AA. It is possible that in the future, we may come to realize that infectious cancer cells and prions are more common than described here. I have also described an exceptional case of a human cancer caused by cancerous tapeworm cells. More surprises on the nature of infectious agents and infections will probably be forthcoming.

Glossary

Agroinoculation Use of engineered *Agrobacterium tumefaciens*, infecting certain groups of plants, as a vehicle to transfer foreign DNA into plant cell nuclei for transient gene expression.

Biolistic bombardment A technique in which gold particles coated with foreign DNA or RNA are delivered under pressure into cells for expression.

BY2 cell A cell line derived from *Nicotiana tabacum* cv Bright Yellow 2. It can be propagated easily in an appropriate culture medium. The cells are fast-growing and nearly translucent. They have been extremely useful for studying viral and viroid replication and for studying basic plant cell biology and gene expression.

Phloem A type of vascular tissue consisting of several types of living cells that is responsible for the long-distance transport of nutrients and signaling molecules in plants. It is also used by viroids and many viruses to spread infection within a plant.

Plasmodesmata Cytoplasmic channels between plant cells that allow cell-to-cell diffusion of small molecules and selective trafficking of RNAs, proteins, viruses, and viroids.

Protoplast A plant cell with its cell wall removed by treatment with cellulase and pectinase, enzymes that degrade the major cell wall components cellulose and pectin. Protoplasts are prepared fresh for each experiment from plant materials or cultured cells and have been extremely useful for studying viral and viroid replication and for studying basic plant cell biology and gene expression.

RNA silencing A mechanism of transcriptional and post-transcriptional gene regulation operating in many eukaryotic organisms. It is mediated by 20–26 nt small RNAs produced from various RNA and DNA sources and functions in regulating RNA stability and translation as well as chromatin modification underlying numerous developmental processes. It also plays a significant role in microbe–host interactions.

Viroid A non-protein-coding and non-encapsidated circular RNA that replicates autonomously in certain plants without the assistance of helper viruses. Some are the causal agents of important diseases.

Virusoid A specific group of viroid-like satellite RNAs, associated with sobemoviruses, that are circular and assume similar secondary structures with viroids. They have no protein-coding capacity (with one possible exception), replicate by utilizing helper viral- and host-encoded factors, and are encapsidated by the helper viral coat protein.

Abbreviations

ASSVd	Apple scar skin viroid
ASBVd	Avocado sunblotch viroid
CCR	Central conserved región
CChMVd	Chrysanthemum chlorotic mottle viroid
CEVd	Citrus exocortis viroid

RYMV	Rice yellow mottle virus

Defining Statement

Viroids and virusoids, the smallest replicons that infect plants, comprise single-stranded, circular (and linear) RNAs of the same size not encoding (with one possible exception) any protein. They represent simple models to study how an infectious RNA replicates in a host cell and spreads systemically to cause diseases, and also are excellent models to investigate the basic structure–function relationships of RNAs.

Introduction

Theodor O. Diener is credited with the discovery in 1971 of the first viroid, potato spindle tuber viroid (PSTVd). This viroid is the causal agent of potato spindle tuber disease first described in the 1920s. Extensive research over the past four decades has established viroids as the simplest form of RNA-based infectious agents. All viroids are single-stranded, circular RNAs with sizes ranging approximately from 250 to 400 nucleotides (nt) and with a compact secondary structure due to their extensive self-complementarity. Differing from riboviruses, these RNAs do not have protein-coding capacity and are not encapsidated in a protein or membrane shell, and differing from satellite RNAs, they do not require the presence of a helper virus to establish infection. Thus, the viroid genomes and/or their derivatives contain all the genetic information needed for replication in single cells and systemic trafficking throughout the host plant to establish infection.

Depending on viroid–host combinations, an infected plant may or may not develop disease symptoms. Common viroid disease symptoms include growth stunting, leaf epinasty and deformation, fruit distortion, and stem and leaf necrosis, leading in the most dramatic instances to plant death. Since viroids do not encode proteins, viroid diseases must result from direct interactions between viroid genomic RNAs or their derivatives and specific cellular components.

Virusoids are also circular RNAs similar in size and secondary structure to viroids, with the evidence available indicating that, with the possible exception of the virusoid of rice yellow mottle virus (vRYMV), they also lack protein-coding ability as well. However, they rely on protein factors encoded by their helper viruses and hosts for replication and/or encapsidation. When virusoids were initially described it was unclear if they were satellite RNAs. They are now regarded as a special group of satellite RNAs associated with certain plant viruses.

Recent research has contributed significant insights into the sequence/structural elements in viroids that are critical for various aspects of replication, systemic spread, and disease induction in an infected plant. Knowledge of potential host proteins that assist various stages of viroid infection is also emerging. Much less is known about the biological functions of virusoids. It is proposed that continuing studies on these subviral pathogens should yield valuable insights into the simplest mechanisms of infection in eukaryotic cells and help uncover the basic principles of RNA structure–function relationships.

Viroid Classification and Structure

There are over 30 species of viroids according to the Ninth Report of the International Committee on Taxonomy of Viruses and numerous sequence variants in the current database. They belong to two families, Pospiviroidae and Avsunviroidae, with their type species being PSTVd and avocado sunblotch viroid (ASBVd), respectively. All viroids are listed in Table 1 under their respective families and genera, and with their abbreviations and sizes.

The distinguishing features of the two families of viroids are summarized in Table 2. Most members of the Avsunviroidae adopt a highly branched secondary structure (Fig. 1(a)), show limited sequence and secondary structural conservation among them, and replicate in plastids (mostly chloroplasts) through a symmetric rolling-circle mechanism involving hammerhead ribozymes embedded in the strands of both polarities. Members of the Pospiviroidae, which generally adopt a rod-shaped secondary structure (Fig. 1(b)) and display conserved sequences among some species, replicate in the nucleus through an asymmetric rolling-circle mechanism not involving hammerhead ribozymes. Five broad structural domains are defined in the secondary structures of some members of the Pospiviroidae, particularly in those forming the genus *Pospiviroid*: the left-terminal, pathogenicity, central, which contains a central conserved region (CCR), variable, and right-terminal domains (Fig. 1(b)).

Host Range of Viroids

Viroids may infect one or a few plant species in the field, as illustrated by the Avsunviroidae, or display a variable host range as in the Pospiviroidae, with hop stunt viroid (HSVd) having been detected in a wide array of herbaceous and woody species. There is

evidence for the recent expansion of host ranges for some viroids. For instance, PSTVd was long known to infect only potato in the field, but more recently it has been reported infecting also avocado, pepper, and tomato. Under experimental conditions, some viroids can infect more species. For example, PSTVd infects *Nicotiana benthamiana* and some specific variants of this viroid also *N. tabacum*. The infected plants may or may not express noticeable symptoms.

Recent studies tested if weedy plant species characteristic for potato and hop fields, which are not natural hosts for PSTVd and HSVd, can be potential hosts for transmitting and spreading infection of these viroids, respectively. Indeed, when the leaves of 12 weedy species from a potato field and 14 from a hop field were inoculated with viroid RNAs or cDNAs through biolistic bombardment, many species supported replication of these two viroids. Sequencing revealed the presence of many variants of these viroids in different infected plant species. Therefore, there is always the potential for viroids to invade new species if conditions permit.

The reasons for the narrow host range of a viroid are not clear. Recent studies suggest a possibility that low level of replication and/or inability to traffic between cells contributes to the limited host range for some, if not all, viroids. For instance, none of the known viroids infect *Arabidopsis thaliana* when inoculated into this plant. In transgenic *A. thaliana* plants expressing the dimeric (+)-RNAs of citrus exocortis viroid (CEVd) and HSVd, members of the Pospiviroidae, replication took place. Agroinoculation of *A. thaliana* with CEVd, HSVd, and coleus blumei viroid 1 dimeric cDNAs showed that these viroids did not traffic from the inoculated leaves to distal plant parts. For some viroids, their host range may be underestimated if disease symptom is used as the main detection method, because their infection of certain plants will not necessarily produce visible symptoms.

Viroid Infection

Viroid Transmission

Like viral infection, in many cases viroid infection easily spreads between individual plants through wounding caused by farming tools, human contact, or plant-plant contact. Some viroids can also be transmitted via infected seeds or pollen. Vegetative propagation by grafts or tubers also readily transmits viroids. For instance, PSTVd can be transmitted by infected potato tubers and infected tomato seeds, and ASBVd can be seed-transmitted in avocado. In contrast to the common transmission of viruses, insect transmission of viroids is not common in the field. There is a report of infrequent transmission of PSTVd by the potato aphid *Macrosiphum euphorbiae*. Quarantine and elimination of infected plant/seed stocks are the most effective means currently available to control the spread of viroid infection.

General Scheme of Systemic Infection in a Plant

The establishment of systemic infection by both families of viroids involves the following mechanistic steps (Fig. 2): (1) import into specific subcellular organelles (the nucleus for the Pospiviroidae and the chloroplast for the Avsunviroidae), (2) replication, (3) export out of the organelles, (4) cell-to-cell trafficking, (5) entry into the vascular tissue, (6) long-distance trafficking within the vascular tissue, and (7) exit from the vascular tissue and subsequent invasion of nonvascular cells to reinitiate the cycle. As discussed further below, some steps have been well studied whereas others remain essentially unknown.

Intracellular Localization and Replication

Pospiviroidae

Before replication, members of the family Pospiviroidae must first enter the nucleus. How this is achieved is still poorly understood. The first study to address this question examined nuclear import of fluorescent-labeled *in vitro* transcripts of PSTVd in protoplasts of tobacco BY2 cells. The protoplasts, prepared by the removal of cell walls via digestion with enzymes such as cellulase and pectinase, were further treated with a detergent such as Triton-X 100 to permeabilize the plasma membrane. When the fluorescent-labeled transcripts were incubated with such protoplasts, they entered the cells through the permeabilized plasma membrane and then accumulated in the nucleus within 15–20 min, which was visualized under a fluorescence microscope. When fluorescent transcripts were mixed with a 10 M excess of non-labeled transcripts, nuclear import of the former was inhibited, suggesting that PSTVd import is a specific and regulated process presumably mediated by a protein carrier that remains to be identified. These findings were confirmed with an independent approach, in which PSTVd could function *in cis* to mediate nuclear import of a large fusion RNA in *N. benthamiana* leaves. Using the latter approach, a subsequent study showed that the upper CCR strand of PSTVd was able to mediate nuclear import of a fusion RNA. The biological significance of this result for viroid infection can now be tested. The cellular factor(s) that recognizes and imports the viroid RNA is not known, and how this RNA exits the nucleus remains to be investigated.

Within the nucleus, viroids replicate via an asymmetric rolling-circle mechanism (Fig. 3(a)). Briefly, the circular (+)-RNA (by convention this polarity is assigned to the most abundant form accumulating *in vivo*) is first transcribed into concatemeric linear (–)-strand RNA in the nucleoplasm. This long RNA then acts as the replication intermediate for the synthesis, also in the nucleoplasm, of concatemeric, linear (+)-strand RNA. In one possible mechanism the latter is transported into the nucleolus, where it is cleaved into unit-length monomers. Subsequent intramolecular end-to-end ligation of each monomer yields the mature,

Fig. 2 Distinct steps of systemic infection of ASBVd and PSTVd. Reproduced from Ding, B., Itaya, A., 2007. Viroid: A useful model for studying the basic principles of infection and RNA biology. *Molecular Plant-Microbe Interactions* 20, 7–20.

Fig. 3 Rolling-circle replication mechanisms of PSTVd (a) and ASBVd (b). The secondary structure sketches of the genomic RNAs illustrate the approximate transcription initiation sites. Viroid: A useful model for studying the basic principles of infection and RNA biology. *Molecular Plant-Microbe Interactions* 20, 7–20.

circular progeny viroid RNA. Alternatively, the cleavage and ligation occur in the nucleoplasm, and the mature viroid RNA is transported into the nucleolus for storage.

Several lines of evidence suggest that the DNA-dependent RNA polymerase II (Pol II) is redirected to transcribe viroid strands: (1) purified tomato Pol II can transcribe a PSTVd template in vitro, (2) CEVd RNAs are associated with the largest subunit of Pol II in vivo, and (3) treatment of cells or nuclear extracts with Pol II inhibitor α -amanitin impedes replication of CEVd and PSTVd in vivo or transcription in vitro. Recent data support that transcription factor IIIA enhances transcription of PSTVd by Pol II. In the past few years, two plant-specific DNA-dependent RNA polymerases (Pol IV and Pol V) and several RNA-dependent RNA polymerases have been discovered. The role of these enzymes, if any, in viroid transcription remains to be tested.

Where transcription initiates in a viroid RNA of the family Pospiviroidae remains to be fully understood. Studies examining the de novo synthesis of the (–)-strand PSTVd RNAs in potato nuclear extracts mapped the transcription initiation site on the circular (+)-RNA to U359/C1 of the left-terminal loop (Fig. 1(b)). This observation was further tested by loss-of-function genetic experiments in combination with biochemical analysis of where the transcription complex binds on the viroid RNA. The importance of the left-terminal loop for replication was additionally supported by the observation that enlargement of this loop by mutagenesis inhibited replication in protoplasts or infection in *N. benthamiana*. Furthermore, disruption of each of three consecutive loops from the left-terminal domain (loops 2, 3 or 4 in Fig. 4), also inhibited replication in protoplasts. The transcription initiation site of the (+)-strand of PSTVd template is yet to be identified.

There are two GC boxes in the PSTVd secondary structure (Fig. 1(b)). Mutational studies suggest that they may play a role in transcription; further studies are needed to determine their functions. There is evidence that loop E located in the CCR of PSTVd (see Fig. 1(b)) is critical for replication. Other studies provided evidence that the PSTVd loop E motif exists in vivo, has a defined tertiary structure, and disruption of this structure leads to loss of function in replication. A more recent investigation using whole genome mutational analysis has identified several additional PSTVd loops as motifs critical for replication in single cells. Some loops are located within the central region (loops 13 and 14 in Fig. 4) and others are located in the left-terminal domain (loops 2, 3, and 4 in Fig. 4). The specific roles of these loops in RNA stability, nuclear transport, transcription, cleavage and ligation need to be determined.

A thermodynamically metastable hairpin II (HP II) structure is predicted to form through base interactions involving nucleotide sequences 227–236 and 319–328 (Figs. 1(b) and 1(c)) during thermal denaturation of the PSTVd secondary structure. The HP II structure has been detected in vitro and in vivo in PSTVd, and it is also present in members of the genus *Pospiviroid*, suggesting its importance in viroid infection. Another metastable structure, HP I (Fig. 1(b) and (c)), is important for PSTVd infection of tomato.

Fig. 4 A genomic map of PSTVd loop motifs critical for replication (R) in single cells or for systemic trafficking (T) in a whole plant. Reproduced, with modifications, from Zhong, X., Archual, A.J., Amin, A.A., Ding, B., 2008. A genomic map of viroid RNA motifs critical for replication and systemic trafficking. *Plant Cell* 20, 35–47, www.plantcell.org. Copyright American Society of Plant Biologists.

However, recent mutational analyses showed that neither HP11 nor HP1 is critical for PSTVd replication in *N. benthamiana*. Whether these metastable structures function in PSTVd infection in some plant species, as supported by previous data, but not in others is an important question in further studies.

The sequence and structural conservation of the CCR in members belonging to the same genera of the Pospiviroidae suggests its potential importance in viroid processing. In vitro studies mapped the cleavage and ligation site of PSTVd between G95 and G96 of the CCR. In a more recent work with transgenic *A. thaliana* plants that express dimeric (+)-RNAs of CEVd, HSVd, and apple scar skin viroid (ASSVd), the in vivo processing site for these viroids was mapped at equivalent positions of a putative HP1/double-stranded structure formed by the upper strand and flanking nucleotides of the CCR. More specifically, the substrate for in vivo cleavage is the proposed double-stranded structure, with HP1 (conserved in the Pospiviroidae, thus supporting its biological significance) potentially facilitating the adoption of this structure, whereas ligation is determined by loop E and flanking nucleotides of the two CCR strands. Cleavage of the conserved double-stranded structure is proposed to be catalyzed by one or more RNases of class III; enzymes of this class also mediate maturation of highly structured nuclear transcripts. Regarding ligation, it has long been known that wheat germ and *Chlamydomonas reinhardtii* contain RNA ligase activities that circularize PSTVd linear RNAs. However, recent data indicate that PSTVd, and presumably the other members of the Pospiviroidae, divert DNA ligase I to act as an RNA ligase.

Avsunviroidae

Viroids of the family Avsunviroidae replicate in plastids. How they enter and exit the chloroplast is not known. Within the chloroplast, these viroids replicate via a symmetric rolling-circle mechanism (Fig. 3(b)). The circular genomic (+)-RNA is first transcribed into a linear, concatemeric (–)-strand RNA. This RNA is cleaved into unit-length molecules and circularized to serve as the template to generate linear, concatemeric (+)-strand RNAs, which are subsequently cleaved into unit-length monomers and circularized. In vitro studies showed that the *Escherichia coli* RNA polymerase can transcribe peach latent mosaic viroid (PLMVd) RNA templates, suggesting that the plastid-encoded bacterial-like multisubunit RNA polymerase (PEP) may be involved in transcription of PLMVd in vivo. However, sensitivity of ASBVd replication to treatment with tagetoxin, and accumulation of PLMVd strands of both polarities in albino sectors of peach leaves wherein PEP is absent, suggests that a nuclear-encoded and phage-like single-subunit polymerase (NEP) is involved in replication in vivo. Further studies on this question are necessary. In any case, like with Pol II in the Pospiviroidae, the chloroplastic RNA polymerase involved is redirected to transcribe viroid strands instead of its physiological DNA template.

The transcription initiation sites have been determined for ASBVd and PLMVd. For ASBVd, in vitro capping and RNase protection assays mapped U121 as the initiation site on the (+)-RNA and U119 as the site on the (–)-RNA. Both sites are located in the AU-rich terminal loops of the RNA secondary structures (Fig. 1). For PLMVd, studies using an adapted RNA ligase-mediated rapid amplification of cDNA ends (RLM-RACE) strategy and analysis of a wide repertoire of PLMVd variants have revealed C51 and A286 as the main transcription initiation sites for the (+)- and (–)-strand RNAs, respectively. The possibility that some variants can start transcription in other sites cannot be formally ruled out.

Members of the Avsunviroidae form hammerhead ribozymes in both the (+)- and (–)-RNA strands that catalyze their self-cleavage in vitro. The general thought is that the concatemeric intermediates of these viroids self-cleave during replication in vivo. However, there is evidence that cellular factors may enhance this cleavage. UV-crosslinking of a viroid RNA–protein complex in infected tissues in conjunction with biochemical analyses identified a chloroplast protein, PARBP33, that interacts with ASBVd in vivo. This protein has an RNA-binding motif and accelerates self-cleavage of concatemeric ASBVd RNAs in vitro. The in vivo role of this factor for viroid replication and general RNA processing remains to be further studied.

Although self-cleavage of both the linear concatemeric (+)- and (–)-RNAs is well demonstrated for members of the family Avsunviroidae, less is known about how monomeric molecules are ligated into circles. Nonenzymatic intra- and intermolecular ligation has been demonstrated for PLMVd in vitro, with this self-ligation producing a 2',5'-phosphodiester bond in vitro. Further studies reported the presence of the 2',5'-phosphodiester bond at the ligation site of the circular PLMVd RNAs isolated from infected peach plants. It will be important to determine whether this mode of ligation functions during PLMVd replication.

A technical advance may enable genetic investigation of the cellular factors involved in cleavage and ligation. When the dimeric cDNAs of three species of the Avsunviroidae, including ASBVd, chrysanthemum chlorotic mottle viroid (CChMVd), and eggplant latent viroid (ELVd), are expressed in the transformed chloroplasts of *C. reinhardtii*, the dimeric (+)- or (-)-RNA transcripts are correctly cleaved into unit length molecules and circularized. There is no evidence for replication to have taken place. Given the complete genome sequence information and well-established genetic and molecular approaches in *C. reinhardtii*, this model system may prove to be of great utility to identify the protein factors important for viroid RNA processing. More recent data have shown that members of the Avsunviroidae recruit for circularization a plastidic isoform of the tRNA ligase; this enzyme has specificity for the 5'-hydroxyl and 2',3' cyclic phosphodiester termini generated by the hammerhead ribozymes and, therefore, appears as an excellent candidate for catalyzing the final step of the replication cycle.

Viroid Cell-to-Cell and Long-Distance Trafficking

To establish a systemic infection, viroid RNAs must traffic from initially infected cells into neighboring cells and distant organs. Studies on PSTVd indicate that cell-to-cell trafficking occurs through cytoplasmic channels (plasmodesmata) and long-distance trafficking occurs through the vascular tissue (phloem). Without encoding proteins, one can assume that viroids either diffuse between cells and through the phloem or they have sequence/structural motifs to mediate the trafficking process. The first clue for motif-mediated trafficking came from studies showing that two mutations in the right-terminal domain of PSTVd do not appear to affect replication in tomato roots, but affect systemic infection. Further studies with microinjection showed that PSTVd could function in *cis* to potentiate cell-to-cell trafficking of a heterologous RNA, suggesting that the viroid RNA has a motif that mediates trafficking. Furthermore, in an infected flower PSTVd traffics into sepals but not into the other floral organs, suggesting that the phloem has a mechanism to recognize and traffic PSTVd RNAs into selective sink organs.

Mutational studies on two PSTVd^{NT} and PSTVd^{NB}, and PSTVd, which differ by 5 nt, identified a bipartite motif that is required for trafficking from bundle sheath to mesophyll, but not in the reverse direction. In addition, this motif is required for trafficking in young, but not in mature leaves. Thus, plant development is also a major factor for the fine-tuning of trafficking controls. Whether the two components of the bipartite motif interact with separate cellular factors for trafficking, or they form a particular tertiary structural motif via conformational changes to interact with a single cellular factor, remains an outstanding question.

A tertiary structural motif, which consists of at least U43/C318 (loop 7 in Fig. 4) that form a *cis*-Watson-Crick base pair with water insertion, is required for PSTVd to traffic from the bundle sheath into the phloem to initiate long-distance transport in *N. benthamiana*. Mechanistically, water insertion distorts the structure of the local helix, with this distortion being necessary for trafficking. This motif recurs in many other RNAs: in rRNAs serves as a binding site for a ribosomal protein. The loop 6 motif of PSTVd is required for trafficking from palisade mesophyll to spongy mesophyll in *N. benthamiana* leaves. This motif has the sequence 5'-CGA-3'...5'-GAC-3' forming three non-Watson-Crick base pairs.

These studies imply the existence of multiple PSTVd structural motifs to mediate trafficking across various cellular boundaries in an infected plant. Indeed, another study has identified many additional loops in the PSTVd secondary structure that are critical for systemic trafficking in *N. benthamiana* (Fig. 4). Closing of these loops by nucleotide substitutions/deletions to create Watson-Crick base pairing abolishes systemic infection while allowing replication. The tertiary structure of each loop, whether each of these loops function individually or in some combinations to mediate trafficking across specific cellular boundaries, and what host proteins interact with each of these loops for function are outstanding issues for future investigations.

A current hypothesis is that certain cellular proteins recognize specific viroid RNA motifs to potentiate trafficking between cells and among organs. These proteins have not yet been identified. Several promising candidates have been reported but their functions remain to be conclusively tested. These include the mobile phloem lectin PP2 from cucumber (CsPP2) that binds HSVd in vitro and in vivo, as well as two phloem proteins that bind ASBVd. A tomato protein, VIRP1, interacts in vitro with the right-terminal region of PSTVd and HSVd, with further work showing that this protein appears to be important for infection. When VIRP1 expression in transgenic *N. benthamiana* is repressed by antisense methodology, the protoplasts prepared from this transgenic plant fail to support PSTVd replication.

Viroid Pathogenicity

Without encoding proteins, viroid diseases must result from interactions between cellular factors with the viroid genome itself or with genome-derived RNAs. Such interactions disturb the normal course of plant development leading to disease onset. Viroid diseases show great variations, depending on viroid-host combinations: they range from nearly symptomless infections to host lethality. One of the most devastating diseases is the cadang-cadang disease, caused by infection of coconut cadang-cadang viroid (CCCVd), that has killed over 30 million coconut palms. Environmental conditions affect symptom expression. In particular, high temperatures and light intensity enhance disease symptoms. No natural resistance to viroid infection has been reported.

In many cases, small sequence or structural variations in a viroid genome can cause symptoms of different degrees of severity (Fig. 5). The viroid RNA structure-disease relationships have been studied most extensively for members of the family Pospiviridae. Early studies with PSTVd and CEVd showed that nucleotide changes in association with different degrees of symptom severity occur in the so-called pathogenicity domain (Fig. 1(b) for PSTVd). More recent studies indicate that all five structural domains play a role in pathogenicity.

Fig. 5 Mild to lethal disease symptoms caused by infection of several PSTVd variants in Rutgers tomato plants. Reproduced from Qi, Y., Ding, B., 2003. Inhibition of cell growth and shoot development by a specific nucleotide sequence in a noncoding viroid RNA. *Plant Cell* 15, 1360–1374, www.plantcell.org. Copyright American Society of Plant Biologists.

Sequence comparisons among ASBVd variants isolated from diseased and healthy tissues of infected avocado suggest that a “U” insertion between positions 115 and 118 is associated with “bleached” tissues. Studies on symptomatic and non-symptomatic variants of CChMVd identified tetraloop UUUC (positions 82–85) as a major pathogenicity determinant. Conversion of this tetraloop to GAAA in natural variants or by site-directed mutagenesis renders the viroid non-symptomatic. In the case of PLMVd, an albinism termed peach calico (PC) is strictly associated with variants containing a specific 12–14-nt hairpin insertion (Fig. 6).

Other than correlations between viroid sequences and symptom severity, little has been known about the mechanisms of pathogenicity until recently. In general, viroid accumulation levels and tissue localizations are not major the factors for the varying degrees of symptoms, suggesting that specific molecular interactions between viroid sequences/structures with host factors are involved in disease mechanisms. The cellular factors that interact with specific viroid sequences/structures for disease development are not known. Infection of tomato by mild and severe PSTVd strains induced or suppressed expression of common and unique sets of host genes. These include genes involved in general defense/stress responses, cell wall structure and metabolism, and chloroplast functions, among others. Similar alteration of host gene expression has also been reported in Etrog citron leaves infected by citrus dwarfing viroid (CDVd). How the altered expression of any host genes contributes to disease formation is not known. PSTVd infection also causes phosphorylation of a protein kinase that is immunologically related to the mammalian interferon-induced, double-stranded RNA-activated protein kinase. Further studies showed differential *in vitro* activation of the mammalian protein kinase P68 by PSTVd strains of different pathogenicity. The biological significance of this activation for viroid symptom expression remains to be understood.

Subsequent studies on PSTVd and PLMVd have started to shed light on the molecular mechanisms underlying pathogenicity. A U257A change in the CCR converted several strains of PSTVd into lethal strains that caused severe growth stunting and premature

Fig. 6 Healthy peach leaf (left) and partial (center) and complete (right) leaf albinism, termed peach calico, incited by variants of PLMVd containing a specific 12–14 nucleotide hairpin insertion. Reproduced with modifications from Navarro, B., Gisel, A., Rodio, M.E., *et al.*, 2012. Small RNAs containing the pathogenic determinant of a chloroplast-replicating viroid guide the degradation of a host mRNA as predicted by RNA silencing. *Plant Journal* 70, 991–1003, www.theplantjournal.org. Copyright Blackwell Publishing Ltd.

death of infected plants (see Fig. 5). The U257A substitution did not alter PSTVd secondary structure, replication levels, or tissue tropism of PSTVd. The stunted growth of infected tomato plants resulted from restricted cell growth, but not cell division or differentiation. This phenotype is correlated positively with downregulated expression of an expansin gene, *LeExp2*, that is known to play an important role in cell expansion in young growing organs. As indicated above, the PC symptomatology, characterized by an extreme chlorosis (albinism) of infected tissues, is associated with the insertion of an extra 12–14 nt sequence that folds into a hairpin in the left-terminal loop of PLMVd. Intriguingly, the insertion occurs sporadically de novo and can be acquired or lost during infection. The presence of this hairpin impairs processing and accumulation of chloroplast rRNAs, eventually affecting the structure and function of the chloroplast translation machinery. Chloroplast development is thus severely disturbed. Still, the underdeveloped chloroplasts retain the capacity to import proteins encoded by nuclear genes, including NEP, and support PLMVd replication. Altogether, these findings sustain the view that specific viroid sequence/structural elements interact with host factors in a highly specific manner to alter host gene expression and developmental processes.

An emerging model for viroid pathogenicity is that small RNAs of 21–24 nt derived from viroid RNA sequences during infection can guide RNA silencing of host genes, thereby leading to development of disease symptoms. Consistent with this hypothesis, there is a positive correlation between the levels of viroid-derived small RNAs (vd-sRNAs) and symptom severity for PSTVd and ASBVd. Moreover, symptom development is correlated with production of vd-sRNAs in some transgenic tomato lines expressing non-replicating, hairpin PSTVd RNAs. However, the correlation between accumulation of vd-sRNAs and symptom expression is not universal. A recent study has provided direct support for the involvement of RNA silencing in PC induction: using deep sequencing, semi-quantitative RT-PCR and RLM-RACE, two PLMVd-sRNAs containing the PC-associated insertion (PC-sRNA8a and PC-sRNA8b) were found to target for cleavage the mRNA encoding the chloroplastic heat-shock protein 90 (Fig. 7). Chloroplast malformations previously reported in PC-expressing tissues are consistent with the down-regulation of cHSP90, which participates in chloroplast biogenesis and plastid-to-nucleus signal transduction in Arabidopsis. Recently, a similar RNA silencing-based mechanism has been proposed for PSTVd and another closely-related viroid: vdsRNAs containing the pathogenic determinants have been involved in symptom induction, although the identity of the primary target is not yet clear.

Virusoids

Viroid-like satellite RNAs are single-stranded molecules found in infected tissues in both circular and linear forms. A singular feature of the viroid-like satellite RNAs of the genus *Sobemovirus* (virusoids) is that the circular form is the predominant RNA encapsidated

Fig. 7 Specific cleavage of peach cHSP90 mRNA mediated by PC-sRNAs. Upper panel, cHSP90 mRNA:PC-sRNA8a duplex (in bold), with the sequence of PC-sRNA8a corresponding to the PC-associated insertion underlined. Arrows mark the cleavage sites predicted and validated by RLM-RACE from five independent clones (fractions indicate number of clones producing the same results). Lower panel, schematic representation of the secondary structure predicted for PLMVd variant C40, with nucleotides complementary to PC-sRNA8a highlighted, and those forming part of the PC-inducing insertion on a black background. Reproduced with modifications from Navarro, B., Gisel, A., Rodio, M.E., *et al.*, 2012. Small RNAs containing the pathogenic determinant of a chloroplast-replicating viroid guide the degradation of a host mRNA as predicted by RNA silencing. *Plant Journal* 70, 991–1003, www.theplantjournal.org. by the viral coat protein, while in viroid-like satellite RNAs associated with members of the genera *Nepovirus* and *Luteovirus* the linear RNA form is predominantly encapsidated. Virusoids bear some structural and functional similarity with viroids but also share biological properties with satellite RNAs. All satellite RNAs must coinfect with a helper virus in order to replicate by utilizing an RNA replicase complex encoded in part by the helper virus and in part by the host. Satellite RNAs have little sequence similarity with the genome of their helper viruses.

Virusoid genomes are 220–388 nt long, assume a rod-shaped secondary structure due to intramolecular base pairing and, with the possible exception of vRYMV, do not encode proteins according to the available evidence. In these aspects virusoids are similar to viroids. However, the thermostability of virusoids is distinct from that of viroids, showing no cooperativity but rather behaving as random base sequences. Virusoids are encapsidated separately from the helper viral RNAs.

Five virusoids are currently known (Table 3). All their helper viruses are members of the genus *Sobemovirus* including RYMV, lucerne transient streak virus (LTSV), subterranean clover mottle virus (SCMoV), velvet tobacco mottle virus (VTMoV), and solanum nodiflorum mottle virus (SNMV). By convention, the encapsidated and infectious form of the RNA is designated as the (+)-strand, which accumulates to higher levels than the (–)-strand that is produced during RNA–RNA transcription. Similarly to viroids, virusoids replicate via a rolling-circle mechanism mediated by hammerhead ribozymes in one or both polarity strands.

There is little understanding of the biology of virusoids, in terms of their interactions with helper viruses, how they initiate replication, how they move between cells and throughout a plant, and how they influence viral disease symptoms. A recent study revealed no involvement of virusoid vRYMV in symptom modulation or ability to break host–plant resistance to the viral disease.

Did Viroids and Virusoids Emerge in the RNA World?

Although in all present cells DNA and proteins store and express the genetic information respectively, with RNA playing just connecting and regulatory roles, the situation differs when descending along the biological scale, with many viruses using RNA as their genetic material. Besides storing genetic information, RNA can express it, as exemplified by the discovery of an increasing number of catalytic RNAs (ribozymes). This dual competence of RNA is the basis for the proposal of an RNA World that preceded the emergence of DNA and proteins. If such a world ever existed, the finding of some sort of survivors in our present world appears as a reasonable assumption. Indeed, viroids (and virusoids) display unique properties consistent with those predicted for the first minimal replicons that might have evolved in the RNA World: (1) small size and high G+C content to cope with error-prone primitive replication, compact folding to enhance survival, and circularity to achieve complete replication without recurring to genomic tags, (2) remnants of structural periodicity suggesting modular assembly into larger genomes, (3) lack of protein-coding ability in agreement with a ribosome-free environment, (4) replication in at least some of them mediated by ribozymes, the key signature of the RNA World and, (5) feasible routes for the transition from the RNA World to a world with proteins and DNA, where the primordial viroids (and virusoids) lost some of their initial abilities and evolved into the plant (and virus) parasites found infecting plants today.

Conclusion

Viroids and virusoids are RNAs small in size, simple in structure, and yet complicated in biological functions. Their replication and systemic trafficking raise the fascinating questions of what RNA structural motifs within the RNA direct all of the biological functions and what host factors are recruited by these motifs to accomplish each function necessary to establish a systemic infection. The viroid disease can be considered as an example of RNA-directed misregulated expression of host genes. Further studies on viroid–host interactions and virusoid–host–helper virus interactions are expected to contribute new and exciting knowledge about the evolution of RNA-based pathogens and about the basic mechanisms of non-coding RNA functions. As compared to viroids, the biology of virusoids has been greatly understudied. It can be anticipated that with appropriate experimental tools developed, virusoids can serve as another powerful set of simple RNA models, like viroids, for fundamental discoveries in biology.

Glossary

Addition mutation Acquisition of one or several nucleotides.

Ambisense coding Said of an RNA genome that can express proteins from either polarity of the same RNA molecule.

Arbovirus Virus transmitted by an arthropod.

Bacteriophage Virus that infect bacteria.

Bottleneck Strong reduction of population size.

Combination therapy Treatment that consists of the administration of two or more drugs.

Complementation Capacity of viral genomes to increase the replicative activity of other genomes through *trans*-acting interactions.

Consensus sequence The sequence that has at each position (nucleotide or amino acid) the most abundant residue at the corresponding position in a set of aligned sequences. The consensus sequence need not coincide with the master sequence, and may not be represented in the population.

Deletion mutation Loss of one or several nucleotides.

Error threshold Average error rate that sets a maximum limit for maintenance of genetic information encoded by a replicating system. Error rates above the error threshold lead to loss of genetic information, also termed error catastrophe.

Evolution Modification of the nucleotide sequence of genetic material as a function of time, independently of the time frame involved.

Frameshift mutation One that changes the reading frame in a coding genomic region.

Genomics The study of genomic nucleotide sequences and their functional and evolutionary inferences.

Homology Quality that defines a common ancestry.

Homopolymer A polymer made of the same monomeric unit. A nucleic acid with a repeated nucleotide.

Hypercycle A system that connects autocatalytic or self-replicative units through a cyclic organization.

Hypermutation Multiple mutations of the same kind, generally introduced in viral genomes by cellular editing activities.

Insertion mutation Gain of one or several nucleotides.

Interference Capacity of viral genomes to reduce the replicative activity of other genomes through *trans*-acting interactions. It can be regarded as the converse of complementation.

Lethal mutagenesis Extinction by an excess of mutations.

LUCA The Last Universal Common Ancestor of present day cellular organisms. It might have been a DNA or a RNA genome with cellular features.

Master sequence The most frequent genomic nucleotide sequence in a mutant distribution because of its higher fitness than the other genomes.

Metagenomics Analysis of the type of genomes that compose a biological community.

Mimivirus A representative of giant viruses, acronym of mimicking microbes viruses.

Mutant spectrum (or mutant cloud, or mutant swarm) The ensemble of mutant genomes that constitute a viral quasispecies.

Mutation (or mutant) frequency The frequency of the total number of mutations or of a specific mutation or mutation type. It differs from the mutation rate in that it is affected by the fitness of the mutated genomes. It is calculated as the total number of mutations counted relative to the consensus sequence, divided by the total number of nucleotides sequenced.

Mutation rate Frequency of occurrence of mutations during genome replication. It is a biochemical event, independent of the fitness of parental and mutated genomes.

Negative selection Process of genome elimination (or maintenance at low frequency) due to low fitness.

Neutral mutation One that does not affect fitness in a given environment. Neutrality is relative to an environment.

Non-synonymous mutation A mutation that gives rise to an amino acid substitution.

Nucleotide diversity Average genetic distance between any two sequences of a population.

Plaque Localized (often circular) region on a cell monolayer made of cells lysed as a result of infection by a single virus particle and virus propagation to neighbor cells.

Plasmid Small circular double stranded DNA that replicates independently of the chromosomal DNA.

Point mutation Replacement of a single nucleotide.

Quasispecies memory Presence in a viral quasispecies of specific subpopulations of genomes that were dominant at an early evolutionary phase.

Rate of fixation (or accumulation) of mutations Number of mutations that become dominant per unit time.

Reassortment In segmented genomes formation of a new genome segment constellation from two different parents.

Replication complex Intracellular site where viral and cellular proteins interact with membrane structures for the replication of viral genomes.

Ribozyme An RNA molecule endowed with catalytic properties.

RNA world It has several meanings in biology. In connection with the present article it may refer to a world that existed prior to the advent of DNA, or to the present day RNA-based part of the biosphere (RNA viruses and other RNA genetic elements).

Synonymous mutation Mutation that does not give rise to an amino acid substitution.

Temperate bacteriophage Bacteriophage whose DNA can integrate into the host DNA.

Transduction Transfer of DNA from one bacterium to another mediated by a bacteriophage.

Transition mutation Replacement of a purine by another purine or of a pyrimidine by another pyrimidine.

Transversion mutation Replacement of a purine by a pyrimidine or vice versa.

Viral fitness Replication capacity of a virus measured relative to a reference isolate or clone of the same virus. A fitness value is relative to an environment.

Virion Viral particle.

Viroid Small circular single-stranded subviral RNA element that infects plants.

Virosphere The part of the biosphere that pertains to viruses.

Abbreviations

DNA	deoxyribonucleic acid
d.str.	double stranded
FMDV	foot-and-mouth disease virus
HDV	hepatitis delta virus
LGT	lateral gene transfer
LUCA	Last Universal Common Ancestor
NCLDV	nucleocytoplasmic large DNA viruses
RNA	ribonucleic acid
s.str.	single stranded

Defining Statement

Metagenomics is providing unprecedented information about viral genomes in different environments, and as viruses replicate in their hosts. The analyses have unveiled a remarkable diversity in genome organization and extreme genetic heterogeneity in the course of infections. Despite accumulating information, it remains challenging to reliably reconstruct the origin of viruses, and their involvement in ancestral evolutionary events. Experimental evolution has contributed insights into the evolutionary mechanisms used by present day viruses that might have been shared by their ancestors. Here we examine observations and proposals.

Early Virus Evolution

Several theories have been proposed for the origin of RNA and DNA viruses, and their connection with the development of the cellular world, beginning with the Last Universal Common Ancestor (LUCA) if a cellular entity with a RNA or DNA genome existed that can be considered the common ancestor of all cells. Two opposite views have been expressed: (i) viruses are descendants of primitive life forms that existed when the cellular world was still under construction, (ii) viruses are late-comers in evolution, and they derived from cells at different points in the process of cellular evolution (Fig. 1). There are arguments in favor and against each of the two assertions.

An Origin Independent of Cells

That the origin of viruses did not require cells as we understand a cellular organization today, even the genetically less complex cells such as mycoplasma, is supported by the presence in viral genomes of genes that do not have an equivalent in present day cells, according to the available data banks. For example, an important group of viruses termed the nucleocytoplasmic large DNA viruses (NCLDVs) [that include the Mimiviruses (a short version of “mimicking microbes viruses” because of their large size) with a 1.2 Mbp genome, that infect some amoebas, and the *Phycodnaviridae* with 160–560 Kbp genomes, that infect algae] share a coat protein

Fig. 1 A possible sequence of major historical occurrences in the origin of viruses and cells. The three large boxes recapitulate several proposals of evolution from a primordial RNA world about 4000 million years ago to the first proto-cells and LUCA. In each box, the left thin arrow suggests a time course of overlapping events. The top schematic trees depict two of several alternatives that have been proposed for the branching of primitive cells into bacteria, archaea and eukarya. In all cases, lateral gene transfers (LGT, horizontal discontinuous lines) are likely to have played an important role. An evolving virosphere is believed to have been involved in the development of the cellular world.

structure characterized by a double jelly-roll fold, similar to a fold found in some viruses that infect the archaeon *Sulfolobus*, and in some single stranded (s.str.) and double stranded (d.str.) RNA viruses that infect eukaryotic cells. This type of coat proteins, together with shared features of other proteins found in viruses but not in cells (termed “virus hallmark proteins”), led to the proposal of “virus self” lineages that would have genome moieties independent from the ones that were the building blocks of cellular genomes. In addition to proteins not represented in cellular data bases, there are other viral genome signatures such as genome size or nucleotide composition that render viruses close to plasmids and distinct from cells. In this scenario, the present day RNA viruses would be the relics of the primitive RNA (or RNA-like) world, while the retroviruses and hepadnaviruses would be remnants of the RNA-DNA transition. The putative virus-like genomes preceded LUCA.

A precellular origin means that viruses were derived from replicating entities that trace back to a primordial RNA world. Prebiological chemical evolution on Earth or elsewhere should have produced molecules that constituted (or evolved into) the building blocks of present day nucleic acids, proteins and lipids. A critical transition should have been primitive RNA structures selected for their capacity of self-replication (Fig. 1). The presence of ribozymes could have favored RNA constructions and phenotypic RNA diversification. Ribozyme activities remain in the present day cellular world (i.e., in ribosomal RNA) and some RNA genetic elements (i.e., in viroids and the hepatitis delta virus (HDV)). The HDV genome appears to have resulted from the conjunction of a viroid-like RNA and RNA with coding capacity. Indeed, in its complementary polarity HDV encodes a protein called “delta antigen”. Viroids and HDV could be traces of lineages belonging to a remote pre-cellular RNA world.

Of particular relevance to current virology is the quasispecies theory that proposed that early replicating entities consisted of mutant spectra, as experimentally found with present day RNA viruses (see Section on “Viral Quasispecies”). Hypercyclic organizations were those postulated to couple two classes of replicating cycles (for example, RNA synthesis and RNA translation to produce proteins) so as to sustain primitive life forms. Coupled organizations might have been embodied in virus-like elements before a pre-cellular organization began to be developed.

Viruses From Cells

The complex organization and elaborate gene expression machineries, together with the dependence of present day viruses upon their host cells and organisms, favors the concept that a cellular world should have been in operation before viruses could arise and be established as successful parasites. In this view, viruses could have derived from cells (initially perhaps RNA cells and then DNA cells) via two types of processes that in their extreme versions have been referred to as escape and reduction. *Escape* means that pieces of cellular genetic material, endowed with self-replication capacity (or that acquired self-replicative elements) might have found their way to a partially autonomous existence with a phase of their multiplication cycle inside cells and a phase outside cells, in the form of transmissible particles (termed virions). *Reduction* means that the number of genes of a cell diminished gradually to reach a simplified subset that maintained the capacity to multiply at the expense of other cells. This would imply a gradual transition from cellular autonomy (to the extent that individual cells can be considered autonomous) towards overt dependence on other cells, in particular for the protein synthesis machinery. The large DNA-containing giant viruses have been viewed as a missing link between a primitive DNA cell and a modern DNA virus.

The capacity to spread, essential for the completion of the life cycle of many viruses we study today, might have been attained first by cells, as observed with “infectious cells” that can be disseminated by insects, perhaps a transmission mode that preceded that of arboviruses. Cell-to-cell transmission of viruses (that nowadays coexists with transmission following an extracellular step) may be a sign of a period when the transmitted entities were cells.

A Primitive Proto-Virus, Proto-Cell Soup

A way to reconcile the two extreme views of virus origins “without cells” and “from cells” is to assume a long time of coevolution of primitive viral forms with pre-cellular entities characterized by a fluid variation in terms of mutation, genomic rearrangements, and lateral gene transfers (LGTs). The participation of vesicles (lipid structures that permitted a primitive compartmentalization that separated “internal” from “external” milieu) favored preservation of genetic elements in mobile, virus-like structures that now we perceive as the “virus self”. Cells under construction exploited related or different genomic blocks, combined with extensive LGT. Vesicles formed in favorable microenvironments such as hydrothermal vents inaugurated the capacity to exchange with the external medium small molecules for energy production to assist in the increasingly complex coupling of an initial metabolism with genome replication. Budding vesicles should have been positively selected because of their capacity to spread replicating molecules and to acquire metabolites for functional testing. DNA viruses might have had an origin independent of RNA viruses, or may derive from RNA viruses, once reverse transcriptase activities were invented. DNA is a chemically more resistant macromolecule than RNA, and it may have gradually become dominant over RNA as the complexity of the genetic material (length and amount of information) increased. The complexity of chromosomal DNA (Fig. 2) necessitated the presence of proofreading-repair and post-replicative repair activities to preserve the identity (physical integrity and encoded information) of large DNA genomes.

We can safely assume that LGT continued late in cellular evolution and that it involved exchanges among cells, and viral elements (Fig. 1). The reason is that different kinds of transfers have been identified or inferred in our present day biosphere (integration of temperate bacteriophage DNA, bacterial transduction, integration of the DNA versions of retroviruses and retroelements into chromosomal DNA, molecular fossil evidence of endogenous retroviruses inserted into the genomes of differentiated organisms, etc.). Remarkably, the fusion of cells to form the primate placenta is triggered by syncytin, a protein encoded in endogenous retroviruses of the HERV-W family. Given the evidence of LGT, it is not surprising that in the cellular descendants we study today related genes can be found in representatives of different domains of life. Present day viral proteins involved in viral genome replication are clustered in the phylogenetic trees, but they are as distantly related to their cellular homologues, as are cellular proteins from different domains of life. Two sets of non-homologous proteins involved in DNA replication can be found, one in bacteria and the other common to archaea and eukarya. This is compatible with their having two independent origins, either from evolving primitive cells or viruses.

Signs of complex exchanges of genetic material among viruses and between viruses and cells include the evolutionary connections between the herpesviruses and the tailed bacteriophages, or the evidence that the NCLDV were built with bacteriophage genes and host cell genes. Different approaches support evolutionary relationships among DNA viruses that infect representatives of the three domains of life. The origin of the eukaryotic cell nucleus has been amply debated, and one of the hypotheses is that it might have derived from a pox-like or Mimivirus-like DNA virus. In fact, the replicative factories of Mimiviruses (the structures where viral DNA replication takes place) have a size comparable to a eukaryotic nucleus. Similar gene expression strategies and regulatory elements such as micro-RNAs are found in cells and viruses. These parallel features speak of common and ancient roots for cells and viruses, and more so considering the geological evidence that several mass extinctions should have eliminated many hosts and their viruses. Present day virosphere is likely to represent a very limited subset of the virus entities that coevolved with cells as they gradually formed the biosphere of differentiated organisms. It is interesting that the term “soup” to designate the

Fig. 2 Representative average diameter values and genome complexity of viruses and some cell types. Viral genomes (depicted as thick outlines inside circles) can be linear, circular, segmented, or multipartite (two or more genome segments encapsidated in separate particles). The bottom boxes describe four groups of viruses according to the type of nucleic acid that acts as replicative intermediate. The figure is modified from Domingo, E., 2016. *Virus as Populations. Composition, Complexity, Dynamics, and Biological Implications*. Amsterdam: Academic Press Elsevier, with permission from Elsevier.

environment of a cell-virus coevolution coincides with the term used by A.I. Oparin almost a century ago to describe sites where inorganic compounds evolved into organic compounds to produce the building blocks of biological macromolecules and the first living cells. Some would argue that the origin of life and of viruses might in fact be related. Although this is a question unlikely to be settled, it is significant that of the four major features that characterize life, namely replication, evolvability, compartmentalization, and metabolism, viruses display the first two.

Attempts to reconstruct the nature of LUCA are challenging, and suggestions have been put forward that it might have been a RNA or DNA cell, without *bona fide* features of a prokaryotic or eukaryotic cell. Equally uncertain are the reconstructions of phylogenetic branches of different domains of life, at post-LUCA times (Fig. 1). What we have learned from the mechanism involved in the evolutionary dynamics of RNA viruses (see Section on “Diversity and Plasticity of Present Day Viruses”) is that the following phenomena might have blurred past phylogenetic relationships: (i) episodes of rapid evolution in primitive cells and viruses; (ii) the availability of multiple molecular pathways for fitness gain: different sets of acquired non-homologous proteins may have achieved comparable functional efficiency; (iii) the occurrence of bottleneck events may have allowed dominance of a molecular solution over others of comparable efficacy; (iv) acquisition of a genomic region from another cell or viral entity may render a prior acquisition useless or even detrimental, and therefore the prior genomic region might be lost, leaving no trace in successful progeny genomes; (v) selective advantages and disadvantages (as a result of point mutations, insertions, deletions, recombination, lateral gene transfers, etc.) are environment-dependent, and the environment changed dramatically over the time periods involved (Fig. 1); (vi) finally we should be aware that distortions of the real events might have been accentuated due to the fact that (i) to (iv) could have happened multiple times over the prolonged time periods involved.

Why Have Viruses Survived to This Date

Viruses may have survived to abound in the present biosphere simply because they parasitized opportunistically cellular organisms, and viruses that encountered a sufficient supply of susceptible hosts were able to persist. In this view, viruses are here merely as selfish elements that persisted blindly, and with no biological function that selected them. A more active role of viruses is implied in an alternative proposal that states that viruses have been positively selected because they promoted variation and diversification of cells, modulation of host population numbers, and they participated in developmental processes. Disease is a secondary consequence of their interactions with their hosts that had a constructive primary function. Expressed as a simple, thought experiment, if

we could compete a biosphere with viruses (as the one we have today) with a biosphere without viruses, for long-term sustainability, the former would be expected to win. Viruses continue performing essential modulatory tasks. To achieve them viruses need diversity commensurate with that of their hosts. There are probably no biological niches devoid of viruses.

Diversity and Plasticity of Present Day Viruses

Present day viruses are diverse regarding genome type (RNA or DNA, single stranded or double stranded, linear or circular, unsegmented or segmented), and in terms of replication strategy (presence or absence of transcription or reverse transcription, ambisense coding, one or multiple messenger RNAs, etc.). According to the nature of the nucleic acid involved in the flow of information during replication (not gene expression) there are four categories of replication cycle, each including important viral pathogens of animals or plants (Fig. 2). Viruses of group 1, those that use only RNA (represented as RNA→RNA), include the RNA bacteriophages MS2 and Q β , many viruses that infect plants such as tobacco mosaic virus, and important human and animal pathogens such as poliovirus, influenza virus, or the hepatitis A and C, Zika, West Nile and Ebola viruses or the hemorrhagic arenaviruses. Viruses of group 2, those that use a DNA intermediate (RNA→DNA→RNA) include the retroviruses, the best studied being the human immunodeficiency virus type 1, the causative agent of acquired immunodeficiency syndrome (AIDS). Viruses of group 3, those that use only DNA in their replicative cycle (DNA→DNA) comprise the tailed DNA bacteriophages (i.e., T4 and λ) which were historically key for the development of molecular biology, as well as salient pathogens such as papillomaviruses, herpesviruses, poxviruses, iridoviruses or adenoviruses, as well as the insect baculoviruses or giant viruses such as the Mimiviruses. Viruses of group 4, those that use RNA as intermediate (DNA→RNA→DNA) include the plant virus cauliflower mosaic virus and hepatitis B virus, termed the hepadnaviruses.

Diversity is also exuberant regarding the ecological niches where viruses are found: any terrestrial and marine environment, including extreme thermophilic and hyper-saline environments, and infecting representatives of all domains of life. The number of viral particles in the biosphere has been estimated in $\sim 10^{32}$, ten times more than the number of cells. In the Earth oceans there is an impressive rate of 10^{23} new infections per second, so that 10^8 viral particles can be counted in each ml of sea water. Most viruses are continually replicating and renewing.

Replication is intimately linked to several types of variations of the genetic material that can affect its evolution. Variations include point mutations, insertions, deletions, cell-dependent hypermutation events, recombination and genome segment reassortment, among others (Fig. 3). For many such events we have also approximate numbers for the rate of occurrence. Point mutation rates for RNA viruses are in the range of 10^{-3} to 10^{-5} mutations introduced per nucleotide copied, and similar or lower recombination rates, depending on the virus. Generally, transition mutations are more frequent than transversion mutations, and at least in the viable genomes that we observe, insertions and deletions (also termed *indels*) are less frequent than point mutations. *Indels* occur more frequently in homopolymeric tracts or repeated sequences. The first high mutation rates determined for RNA viruses were unexpected at a time when mutations were considered rare events in the biological world, and procedures for the analysis of genetic material at the molecular level were not available. High mutation rates originate from the absence or low efficiency of proofreading-repair activities in the polymerases that catalyze their replication. These mutation rates are about one million-fold higher than those typically observed during replication of chromosomal DNA, marking a striking difference between the DNA-based cellular world and the RNA virosphere.

Although quantification of many types of genome variations are lacking, current evidence, obtained mainly from deep sequencing, suggests that variations occur exuberantly, and that we observe only a minimal proportion of those that occur during viral genome replication. Many genomes modified by mutation or recombination are eliminated (or kept at low frequency) by negative selection because they inflict a fitness cost. It is expected that similar mechanisms of genome variation operated in the ancestral times when the cellular and virological worlds were under construction (Fig. 1). It can be suspected that early polymerases (be RNA- or protein-based) had a more relaxed nucleotide discrimination than present day enzymes. It is also likely that proofreading-repair and post-replicative repair activities – that preserve the identity of present day large cellular and viral DNA genomes – evolved with the increase of complexity of genetic information. Therefore, we conjecture that at the times of the primitive proto-virus, proto-cell soup, mutation rates were generally high, and that all living matter was much more fluid in terms of genetic instability and genetic exchanges than today. Although it is unlikely that such a proposal can ever be proven in a definitive way, relevant information may come from metagenomics and the use of analytical methods based on computations with increasing power.

Evolutionary Dynamics

Our understanding of virus evolution is founded on two main general approaches: (i) determination and comparison of nucleotide (and deduced protein) sequences, and (ii) design of experiments in which evolutionary events can be tested under controlled laboratory conditions, referred to as experimental evolution. Approach (i) is based upon the determination and comparison of nucleotide sequences of virus from multiple sources: environmental samples (soil, water, cellular organisms without disease symptoms), and infected hosts as they manifest disease symptoms. Sequence information is complemented with virus isolation, purification of viral particles, and functional and structural studies. Comparative structure-function relationships of encoded proteins and viral particles may assist in the establishment of connections among viruses which are distant at the genomic level.

Fig. 3 Representation of genetic modifications that can alter viral genomes. (A) Major types of mutations in RNA (made of the standard nucleotides A, G, C and U as building blocks) and DNA (with T instead of U). A genome is depicted as an elongated rod. Symbols on the rod (cross, circle and line) represent mutations. A fragment inserted or deleted from the genome is depicted as an empty rod. (B) Recombination (formation of mosaic genomes) is found in DNA and RNA genomes. Here, two mechanisms of recombination are shown for RNA. RNA polarity is indicated by + and – symbols. Replicative recombination is the result of template switching during template copying. Nonreplicative recombination is depicted as the outcome of ligation (joining) of RNA fragments. (C) Segment reassortment takes place in segmented genomes. The example shown here refers to human influenza virus type A. In the new segment constellation six genomic segments originate from one parent (blue) and two from the other (gold). The figure is modified from Domingo, E., 2016. *Virus as Populations. Composition, Complexity, Dynamics, and Biological Implications*. Amsterdam: Academic Press Elsevier, with permission from Elsevier.

Approach (ii) consist of a wide range of experimental designs aimed at interrogating viral populations regarding their evolutionary potential, and response to selective constraints interposed in their infectious cycles.

Inferences From Genomics and Structure

The International Committee on Taxonomy of Viruses (ICTV) in its 2017 report divides known viruses in 10 Orders, and each of them is subdivided in families (in some cases also subfamilies), genera, and species. Unless viruses belong to the same species, nucleotide sequence identities are too tenuous to establish reliable phylogenetic relationships that could relate present day DNA or

RNA viruses. Not only point mutations but also signs of ancestral recombination and lateral gene transfer events render the establishment of phylogenetic relationships for the virosphere extremely challenging. A pan-virus phylogeny is not within reach. However, the fundamental observation that protein structure evolves far more slowly than the corresponding coding sequences, permits the proposal of virus groupings based on the presence of functionally related proteins or in similarity of three dimensional structures of encoded proteins, including the viral capsid. These approaches have grouped large DNA viruses in three distinct categories: the nucleo-cytoplasmic large DNA viruses (NCLDVs), the herpesviruses and the baculoviruses.

It should be emphasized that while phylogenetic relationships inform of the natural history of viruses and their possible ancestors, a given phylogenetic position is not necessarily associated with disease characteristics. This is illustrated by examining the 2017 ICTV report. The order *Picornavirales* includes 7 families, one of them being the *Picornaviridae* that are divided into 40 genera, one of which, the *Aphthoviruses*, comprises four species: bovine rhinitis A and B viruses, equine rhinitis A virus, and FMDV. It is obvious from their names that the representatives of these viral species do not share host specificity or disease symptoms. The lack of correlation between phylogenetic position and disease potential is part of a general indeterminacy of biological behavior in connection with genomic features. Specifically, regarding viral pathogenesis, one or a few amino acid substitutions have been associated with changes in virus-host interactions (i.e., receptor recognition, capacity to replicate in some cell types, capsid stability, particle transmissibility, etc.) that bear on disease potential. Thus, a limited number of genomic changes can enhance or decrease virulence without modifying the phylogenetic position of a virus.

Inferences From Experimental Evolution

Viruses that can be adapted to cell culture can be used to establish cytolytic or persistent infections in established cell lines, primary cells, organ explants or entire host organisms. These designs have served to understand the response of viral populations to environmental changes (pH, temperature, ionic strength, host cell types, etc. in cell cultures, or host species and their immune status *in vivo*), or to externally applied selective constraints (drugs, antibodies, etc.). In many cases quantifications of drug and antibody resistance have been performed, with obvious implications in clinical virology, and for the planning of antiviral treatments and vaccine design. Overall, these studies have supported a remarkable capacity of viruses to respond to constraints for survival, in particular the highly variable RNA and single-stranded DNA viruses for which evolutionary events can be recorded in days, and sometimes even in hours. They are excellent systems to establish basic principles of evolution.

Several concepts that originated in population genetics have found support in experimental studies with RNA viruses. An important concept is Muller's ratchet, or fitness decrease by the irreversible accumulation of mutations postulated for asexual organisms. Indeed, in model experiments consisting of repeated plaque-to-plaque transfers (a way to mimic sequential bottleneck events in the laboratory) viral genomes accumulated mutations concomitantly with average fitness decrease. These studies revealed also that multiple mutational pathways are available to a virus for fitness gain, supporting once again a remarkable flexibility for survival. Other important concepts such as the Red Queen hypothesis (parallel fitness gain in competing populations) or the competitive exclusion principle (inability of different evolving populations to coexist for prolonged time periods using the same resources) have found support in experiments with RNA viruses.

Dissection of the composition of viral populations as they replicate in infected hosts was achieved traditionally by molecular cloning (in standard vectors such as bacterial plasmids) of viral genomes (or genes of interest within viral genomes), followed by traditional Sanger sequencing of the individual clones. More recently, application of deep sequencing methodologies has permitted further penetration into the composition of mutant spectra. Despite such procedures analyzing a limited sample of the viral populations under study, they have documented that populations of RNA viruses and some DNA viruses consist of extremely complex collections of mutant genomes as a consequence of high mutation rates, and the capacity of viable genomes to accept part of the newly arising mutations. Mutant distributions are generated rapidly, even following a bottleneck event, during host-to-host transmission (Fig. 4). The mutant spectrum changes displayed in Fig. 4 may explain a frequent observation made with pathogenic viruses, that the rate of virus evolution within individual hosts (intra-host evolution) measured as the number of mutations accumulated per unit time, is significantly higher than the rate calculated for the same virus at the epidemiological level, when multiple transmissions have taken place in the field (inter-host evolution). The fact that viruses replicate as mutant distributions has several implications for clinical virology and the control of virus disease. Also, interestingly, the finding of extreme genome heterogeneity approximates present day viruses to the type of population structure postulated for the primitive replicons at the onset of life (bottom box in Fig. 1). This remarkable connection deserves further discussion.

Viral Quasispecies

Both DNA and RNA viruses are continuously evolving in the present day biosphere as friendly symbiotic partners or as agents of disease. High mutation rates determine that a progeny genome cannot be identical to the corresponding parental genome that served as template for replication. Both in nature and in laboratory preparations RNA viruses and some DNA viruses are found as collections of closely related genomes that may differ in several mutations. The mutant ensembles, mutant spectra or mutant clouds are termed viral quasispecies (Fig. 5), and their complexity (how many mutations distinguish individual genomes) can be quantified by several diversity indices (i.e., mutation frequency or nucleotide diversity). The viral quasispecies concept is an extension to viral genomes of a general theory of molecular evolution formulated by M. Eigen, P. Schuster and their colleagues

Fig. 4 Mutant distributions during infection and transmission. An infected individual includes a spectrum of mutants, not a repeated genomic sequence, due to high mutation rates during viral replication. Transmission events and intra-host evolution are represented by long and short arrows. Only a subset of the genomes is efficiently transmitted from the donor (individual with black outline) to the recipient (brown outline). The virus in the recipient individual replicates and broadens its mutant spectrum. Again, only a subset of genomes from this mutant spectrum that resemble the ones in the first transmission are efficiently transmitted to the third individual (green outline). The net result is that rates of evolution will appear as slower than those within each host. Taken from Domingo, E., 2016. *Virus as Populations. Composition, Complexity, Dynamics, and Biological Implications*. Amsterdam: Academic Press Elsevier, with permission from Elsevier.

Fig. 5 A representation of viral quasispecies. Genomes (from the same replicative ensemble or the same infected host) are represented as horizontal lines and mutations as symbols on the lines. Note that the master (dominant) sequence in the mutant distribution on the left does not coincide with the consensus sequence. The representation on the right illustrates that a seemingly random distribution of genomes can be divided into six categories of different abundance given by the size of the spheres. The figure is modified from Domingo, E., 2016. *Virus as Populations. Composition, Complexity, Dynamics, and Biological Implications*. Amsterdam: Academic Press Elsevier, with permission from Elsevier.

to understand self-organization and adaptability of primitive replicons at the early stages of life development prior to the advent of proto-viruses and proto-cells (Fig. 1).

The application of quasispecies theory to virology has helped in the interpretation of many observations in infections both in vivo and in cell culture, regarding the way viruses respond to selective constraints. The biology of RNA viruses is influenced by the dynamic, continuously changing repositories of viral mutants that cannot be captured by studying consensus sequences alone. Examples of mutant spectrum-dependent implications are: (i) change in cell tropism due to mutations that can alter cell receptor specificity, (ii) capacity to respond to external constraints such as antiviral therapies due to the preexistence, or newly generation of viral mutants, (iii) capacity to overcome immune responses, (iv) reversion of attenuated virus vaccine strains to virulence, (v) the presence of a molecular memory in the form of genomes that are present as minorities in a mutant spectrum, but that were dominant at an early phase of evolution of the same lineage. Memory is a reflection of viral quasispecies behaving as complex adaptive systems. A hallmark of quasispecies is that the components of a mutant spectrum may engage in positive (complementation, cooperation) or negative (interference) interactions that affect the behavior of the ensemble. Internal interactions reinforce the notion of mutant distributions acting as “units of selection”, as implicit in quasispecies theory.

A corollary of quasispecies theory is the so called error threshold relationship that states that for any replicative system there is a maximum mutation rate compatible with maintenance of genetic information. Exceeding this limit (a transition often termed violation of the error threshold) results in loss of information. Applied to viral populations, this prediction has been experimentally verified by achieving virus extinction with mutagenic nucleotide analogues that elevate the mutation rate above the maximum tolerable limit. This is now an active area of antiviral pharmacology termed lethal mutagenesis. The transition toward virus extinction occurs through an expected increase of mutation frequency, but, most significantly, without any modification of the consensus sequence. In other terms, a profound modification such as loss of infectivity (the ultimate goal of an antiviral intervention) can be achieved without any modification of the consensus sequence. The relevance of mutant spectra for the understanding of viral dynamics is evident.

Quasispecies is an active field of research, both at the theoretical and experimental level. Extensions of quasispecies theory to complex cellular organisms in variable fitness landscapes are compatible with any of the mechanisms of genome variation described for viruses, including recombination and genetic exchanges (Fig. 3). It is tempting to propose that the type of quasispecies dynamics at play with present day viruses might have been the norm in the developing cellular world portrayed in Fig. 1, in epochs still devoid of repair mechanisms for genetic systems, including pre-cellular assemblies. This should have provided a propensity for episodes of error catastrophe, but also extreme plasticity together with complementation and cooperation relationships, to explore molecular pathways for fitness gain. Unfortunately, such flexibility rendered extremely difficult the reconstruction of past events. What we analyze in the present day biosphere and virosphere may be tiny remnant samples of an exuberant complexity that has been lost forever.

Summary and Prospects

Viruses are continuously evolving in the present day biosphere, and there is no reason to suspect that they were not evolving in the past, even at faster rates. The mechanisms of molecular evolution of viruses that we have characterized during the last decades are similar to the mechanisms used by cells. In particular, present day gene transfers and integrations of viral genomes into cellular DNA probably reflect transfers that have occurred among viruses and cells at all times during their generation and gradual increases of complexity. Indications are that fluidity of the living world might have been even more exuberant in the remote past than today.

These arguments can be proposed thanks to results brought about by salient methodological developments. Indeed, the introduction of molecular tools to the study of evolution in the second half of the 20th century changed dramatically the views on the role of genetic change in the present day evolution of organisms. We are aware now that we live in a plastic biosphere that exploits a range of mechanisms of adaptation to different environments, while being subjected also to random events, fundamentally in the form of bottlenecks that accentuate genetic drift. However, the adaptive pluripotency has a cost. Viral disease can be viewed largely as a process of virus adaptation to multiply in tissues and organs of differentiated host organisms, resulting in perturbation of essential and non-essential (referred to as “luxury”) cellular functions. The adaptive capacity not only of viruses but also of many cellular types (bacteria, eukaryotic monocellular parasites, tumor cells, etc.) underlies their persistence and disease potential. Mutator bacteria (those that display enhanced mutation rates) pose a specific threat, and both antiviral resistance in viruses and antibiotic resistance in bacteria are major public health concerns. Microbial resistance, genetic disease or cancer are all mediated largely by the same evolutionary mechanisms (mutation, recombination, genetic exchanges, and resulting population heterogeneities) that appear to have presided viral and cellular evolution over eons.

Current evolutionary dynamics for viruses is easier to dissect than the events that took place in the past. However, an expectation is that mounting information from genomics and proteomics of present day organisms, conjointly with bioinformatics tools and increasing computational power may assist in the reconstruction of past events. Improvements may also come from application of deep sequencing technologies that can be focused not only on the most abundant representatives of the biological world but also on viral and cellular minorities that may be hiding in environments still to be explored. Viral or cellular subpopulations that are a minority in one environment might be mobilized and driven towards dominance to face adaptive needs. This is becoming clear for RNA viruses but may be also true of other viruses and cell populations. There is increasing evidence of cellular heterogeneities whose possible biological relevance remains largely unknown.

The present status of knowledge about evolution indicates that the once considered static DNA biosphere (made of DNA cells and DNA viruses) is actually much more variable than thought. Genome rearrangements, recombination, LGT, participation of mobile elements and subcellular entities, render DNA and its environments remarkably dynamic. Expressed in simple terms, an “extremely” dynamic RNA biosphere coexists with a dynamic DNA biosphere. Molecular analyses have also unveiled a difference between the modifications that actually occur in viral and cellular genomes, and those that we observe. As a final summary statement, the study of viral evolution has furnished new insights into the evolutionary history of life on Earth, and it has reinforced the need to consider Darwinian principles for the control of viral disease.

Glossary

BCC Business Communications Company Inc., a leading US information resource producing detailed market research reports, newsletters, and conferences.

FDA Food and Drug Administration, an agency of the United States Department of Health and Human Services responsible for regulating *inter alia* food and dietary supplements.

Oleoresin A coloring or flavoring plant extract obtained by solvent extraction.

PUFAs Polyunsaturated fatty acids, a chemical group of substances containing some essential nutrients originally termed vitamin F.

Retinol Animal form of vitamin A derived from animal retinyl ester precursors or plant provitamin A carotenoids.

Saccharomyces cerevisiae A species of budding yeast traditionally used in baking and brewing and a well-studied eukaryotic model organism.

Sapropel A version of microbial transformation wherein DNA (or RNA) is returned to a species in which it could naturally occur, thereby the nucleic acid used may have been subject to modifications producing a novel order of genes or control elements like promoters or multiple gene copies.

Self-cloning A version of microbial transformation wherein DNA (or RNA) is returned to a species in which it could naturally occur, thereby the nucleic acid used may have been subject to modifications producing a novel order of genes or control elements like promoters or multiple gene copies.

Nomenclature

AMP	adenosine monophosphate
BCC	Business Communications Company Inc.
DHBP	3,4-dihydroxy-2-butanone 4-phosphate
DRL	6,7-dimethyl-8-ribityllumazine
FAD	flavin adenine dinucleotide
FDA	Food and Drug Administration
FMN	flavin mononucleotide
gluc-6p	glucose-6-phosphate
GMP	guanosine monophosphate
GRAS	generally recognized as safe
GTP	guanosine triphosphate
IMP	inosine monophosphate
2KGA	2-keto-L-gluconic acid
PUFA	polyunsaturated fatty acid
ribu-5p	ribulose-5-phosphate
XMP	xanthosine monophosphate

Defining Statement

Studies on the worldwide nutritional status repeatedly reveal vitamin deficiencies and a need for their dietary supplementation. Also, with an increasing number of reported beneficial health effects, the growing vitamin market demands cost-efficient production processes, employing genetically engineered microorganisms as alternatives to chemical synthesis.

Applications and Market

Vitamins, a chemically heterogeneous group of organic compounds essential for an organism, are by definition substances that are not or only inadequately provided by the organism's anabolism. These nutrients fulfill catalytic or hormone-like functions, and thus

[☆]Change History: October 2016. Klaus-Peter Stahmann updated text, some figures in Table 1, and added references.

This article is an update of S.M. zu Berstenhorst, H.-P. Hohmann, K.-P. Stahmann, Vitamins and Vitamin-Like Compounds: Microbial Production, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 549–561.

a daily dietary intake of small amounts satisfies the requirements. Apart from a catalogue of symptoms caused by vitamin deficiency, nowadays vitamins have gained additional attention due to numerous preventional health benefits, for example, in neoplastic diseases like cancer or degenerative diseases like rheumatism. In developed countries, a more than sufficient and seasonally independent food supply of all vitamins and vitamin-like compounds is available – if only the consumer chooses the right diet. However, studies repeatedly reveal inadequate nutrient intakes, even if situations creating increased requirements like pregnancy, certain pre-existing medical conditions, and an unhealthy lifestyle are made allowances for. A balanced and varied diet should contain nutrient-rich fruit and vegetables, milk and grain products, as well as sea fish and low-fat meat. According to the large-scale eVe Study, nearly 50% of the Spanish population need to adjust their usual food pattern toward a more nutrient-dense, healthier diet. Shortages in single vitamins or combinations of riboflavin, folate, vitamin A, vitamin D, vitamin E, and vitamin C were found in a high proportion of the 10,208 participants. Although the pattern of inadequate vitamin intake varies between populations, it is a worldwide problem causing a demand for additional, industrially produced vitamins.

After the isolation of all 13 vitamin groups by extraction techniques in the 1930s and 1940s, structure determinations of the vitamins led to the development of chemical synthesis procedures, culminating in several Nobel prizes. However, today vitamins are produced by chemical synthesis, extraction chemistry, biotechnical or combined methods, in which biotechnical procedures comprise fermentation or bioconversion processes. Production scales and methods of syntheses of these compounds within the scope of this article are compared in Table 1. Although only the polyunsaturated fatty acid (PUFA) arachidonic acid, vitamin B2, and vitamin B12 are produced exclusively by biotechnical processes, the development of further microbial techniques to replace chemical synthesis is also pursued. Several factors like increasing ecological awareness and environmental constraints, sustainability of renewable resources, and consumer demand for naturally produced products have an impact. However, regarding the latter, no scientific data support a significant difference between chemically and natural derived vitamins, as stated by the Health and Consumer Protection Directorate-General of the European Commission in 2003 for the pigmentation of fish by astaxanthin synthesized chemically or originating from the natural source *Xanthophyllomyces dendrorhous*. But, increasing costs of fossil resources and disposal of chemical waste count in favor of biotechnical processes, since not only is there a need for an efficient process of manufacture but also one that makes a handsome profit for a company in the international market.

This article focuses on vitamins and vitamin-like compounds, whose microbial production already is commercially relevant, with emphasis on the production of vitamin B2. Subsequently, the current state of industrial development of other vitamins is discussed and the impact of the so-called white biotechnology on our daily life and on industry is considered in the Section 'Conclusions and outlook'.

The world market value of vitamins and vitamin-like compounds is estimated at nearly US\$2.3 billion by 2007. As a result of the entry of Chinese competitors in the market sales fell from US\$2.7 billion in 1999 even though the market was still growing by approximately 4% annually. Interestingly, however, the market volume of vitamins is still a multiple of that of antibiotics. The leading vitamins are E, C, and A, summing up to more than 65% of total sales in 2002. In general, the majority of industrially produced vitamins are used in animal feed, with a share of almost 50%. The supplement and food industries follow with 22 and 17%, respectively, and 11% is used in cosmetic products. The percentage in pharmaceutical and technical applications is marginal.

An increasing demand for feed vitamins is caused by the growing world population going along with factory farming ashore and at sea, in which the fodder, especially conserved feed, needs vitamin supplementation to enable a healthy and competitive livestock. Moreover, people directly consume almost 40% of all vitamins produced either as dietary supplements or as fortified foods. Indeed eating habits, lifestyle, some medical conditions, and food processing or preservation methods render additional vitamin intake useful. Additionally, the positive appeal of vitamin enriched products is boosted by scientific and public reports about their beneficial health effects. Thus nowadays vitamin fortification of industrially produced food to increase nutritional value is very common, with breakfast cereals and fruit juices being typical examples. In parallel, the market for dietary supplements in the form of tablets, powder, or liquids is rapidly growing: according to a Forsa survey in 2000 every third German regularly consumed dietary vitamins with annual costs of €300 on average. The consideration of vitamins as a panacea creates a never-ending debate about the pros and cons of dietary supplementation of vitamins. Pharmaceutical applications like drip-feeding and prescription of vitamins account for less than 1% of the vitamin market.

Table 1 Industrial production of vitamins and vitamin-like compounds showing significant impact by microorganisms

Compound	Production method				World production (tons per year)
	Chemical synthesis	Extraction (chemical)	Microbial	Combined	
Fat soluble					
Carotenoids	+	+	+	+	>1,000
PUFAs		+	+		>1,000
Water soluble					
Vitamin B2			+		<10,000
Vitamin B12			+		<100
Vitamin C				+	>100,000

Table 2 Microorganisms applied for large-scale production of vitamins and vitamin-like compounds

Compound	Production microorganism			Percentage of world production
	Bacteria	Fungi	Microalgae	
Fat soluble				
Carotenoids				
β-Carotene		<i>Blakeslea trispora</i> ^a	<i>Dunaliella salina</i> ^a	15
Astaxanthin		<i>Xanthophyllomyces dendrorhous</i> ^{a,b}	<i>Haematococcus pluvialis</i> ^a	<10
PUFAs				
Arachidonic acid		<i>Mortierella alpina</i>		<10
Docosahexaenoic acid or Eicosapentaenoic acid		<i>Yarrowia lipolytica</i>	<i>Thraustochytrium</i>	<10
Water soluble				
Vitamin B2	<i>Bacillus subtilis</i>	<i>Ashbya gossypii</i> ^a		100
Vitamin B12	<i>Pseudomonas denitrificans</i> ^a			100
Vitamin C ^c	<i>Gluconobacter suboxydans</i> ^a and <i>Ketogulonicigenium vulgare</i> ^{a,d}			50

^aNatural overproducer modified by strain improvement.^bOriginal name: *Phaffia rhodozyma*.^cThe bioprocess yields 2-keto-L-gluconate from which L-ascorbic acid, the γ-lactone, is derived by a chemical downstream step.^dOriginal name: *Gluconobacter oxidans*.

In contrast to the pharmaceutical industry where highly purified vitamins are applied the feed industry, being the principal client, takes an additional advantage of microbial production: biomass residua rich in lipids and proteins represent extra nutrients and thus less purified vitamins have a positive feeding effect. In case of vitamin B2 and the carotenoid astaxanthin, even poor qualities of such vitamins that have residual biomass are being sold, and for which the extraction procedure is simplified and the chemical load is reduced. Nevertheless, although all vitamin productions in microorganisms must be licensed they must also have generally regarded as safe (GRAS) status.

Microorganisms used in industrial scale production of vitamins belong to bacteria, microalgae, or fungi. In classical approaches microbial vitamin production starts with a natural overproducer, such as the fungus *Ashbya gossypii*, rich in vitamin B2. To improve the yield successive rounds of mutagenesis and selection are carried out along with optimization of process parameters. Apart from classical strain improvement, modern biotechnology allows genetic engineering of many microorganisms that are already approved for use in other industrial processes. Their metabolic engineering for application in a vitamin manufacturing process is facilitated by increased knowledge of the biochemical and regulatory pathways in these microorganisms. In-depth analyses of enzymes and their substrates with regard to flux control and genome-wide transcriptional analysis allow further optimization if genetic engineering is feasible and the genomic DNA sequence is known. Nevertheless, most industrial strains still are based on improvement of natural overproducers. Only a few, most impressively *Bacillus subtilis* in the vitamin B2 production process, are a result of sophisticated genetic engineering (Table 2).

The efficiency of microbial vitamin production is very diverse. Final product titers range from about 100 mg L⁻¹–100 g L⁻¹. The yield, that is, conversion of the carbon source into the final product, ranges from inefficient to highly efficient. Especially when phototrophic microorganisms are used, turnover time and concentrations are low, a large production area is needed, and downstream processing is cost-intensive. Although strains and production processes are continuously optimized, some biotechnical procedures are used only for production of niche products in comparison to chemical methods. Examples include high-quality stereo-specific carotenoids and PUFAs as dietary supplements in infant formulas.

Fat-Soluble Compounds

Carotenoids

Carotenoids are organic pigments naturally produced by microorganisms and plants. They fulfill diverse biological functions like energy transfer in photosynthesis, photoprotection, species-specific coloration, and supply of precursors, for example, in the biosynthesis of vitamin A. They consist of a long carbon backbone derived from isoprenoid moieties. In many cases, both termini form ring systems. The extended system of conjugated carbon-carbon double bonds is responsible for the light absorption and the bright color of the carotenoids. The over 600 different carotenoids described so far fall into two main groups: the carotenes, non-oxidized hydrocarbon carotenoids, and the xanthophylls, oxygenated carotene derivatives. Following the isoprenoid pathway, natural carotenoid synthesis either starts from acetyl-CoA via mevalonate or from deoxyxylulose-5-phosphate, a condensation product of pyruvate and glyceraldehyde-3-phosphate.

Less than a dozen carotenoids are produced industrially from vegetable sources or petals, by fermentation, or by chemical synthesis, the latter providing for the bulk amount of carotenoid demand worldwide. Lutein-containing oleoresins from *Tagetes erecta* grown in large scale mainly in India and China are extensively used for egg yolk and broiler pigmentation. Despite numerous intensive efforts to develop classically improved or genetically engineered carotenoid production strains, microbial carotenoid production is very limited, although the construction of the first recombinant carotenoid-producing *Escherichia coli* strain dates back almost 30 years ago. By contrast a sheer unlimited source for commercial β -carotene production could be crude palm oil, if cheap extraction methods to recover the highly diluted product from the oil could be developed.

Apart from being used as food colorants and animal feed supplements for poultry and aquaculture, carotenoids play an increasing role in cosmetic and pharmaceutical applications due to their antioxidant properties. The pigments are often regarded as the driving force of the nutraceutical boom, since they not only exhibit significant anticarcinogenic activities but also promote ocular health, can improve immune response, and prevent chronic degenerative diseases.

β -Carotene

The nutritional role of carotenoids in human diet is best understood in the context of their provitamin A activity. About 50 carotenoids are known that can function as provitamin A, of which β -carotene is the most efficient one. There are several colorful fruits and vegetables rich in the red-colored β -carotene, examples of vegetables include carrots and sweet potatoes, but the best source is food derived from animals, especially liver and whole milk. A daily intake of 3–6 mg of β -carotene is estimated to ensure a beneficial blood concentration of retinol equivalents, the animal form of vitamin A.

β -Carotene is an important industrially produced carotenoid. As estimated in a Business Communications Company Inc. (BCC) report of 2005, β -carotene accounted for roughly a quarter of the total carotenoid sales in 2004, totaling about US\$242 million. DSM Nutritional Products (Switzerland) and BASF (Germany) dominate the market with their chemical synthesis processes, but Chinese competitors are catching up.

Microorganisms account for about 15% of industrial β -carotene production. Vitan Ltd. (Ukraine) and Vitatene (Spain) use the heterothallic zygomycete *Blakeslea trispora*, producing, after intensive classical strain improvement by random mutagenesis and selection, according to patent literature, up to 7 g L⁻¹ β -carotene in large-scale fermentations. Pigment production and accumulation is stimulated by several sex-specific pheromones, for example, trisporic acids, the synthesis of which commence after inoculation of the production fermenters with both *B. trispora* mating partners. The high β -carotene accumulation of 4% or more within the *B. trispora* biomass might be facilitated by the cell's high triglyceride content. Filtration after the fermentation process, solvent extraction of the dried biomass, and crystallization result in a pure product.

An alternative natural β -carotene producer of commercial interest is the halophilic green microalgae *Dunaliella salina*. It accumulates the pigments in oil globules in the chloroplast interthylakoid spaces, protecting them against photoinhibition and photodestruction. AquaCarotene Ltd. and Cognis take advantage of large, shallow ponds with high salinity in Western Australia that are exposed to intense solar radiation, in which the microalgae are cultivated. Other companies like Nature Beta Technologies with a production site in Israel employ open channels in the form of oblong raceways agitated by paddle wheels. Closed tubular systems are in an experimental stage. Excessive pigment formation in *D. salina* is achieved by numerous stress factors like high temperature, lack of nitrogen and phosphate but excess of carbon, high light intensity, and high salt concentration, the latter two having the highest impact. Whereas in open ponds β -carotene accumulates in the 100 mg m⁻³ range, the obviously more capital-intensive raceway ponds can deliver up to 15 g m⁻³. An average yearly productivity of around 200 mg m⁻² day⁻¹ has been reported. Harvesting the biomass present at low concentration in the corrosive cultivation brine, for example, by filtration after flocculation, requires special attention. Dried *D. salina* biomass for sale contains 10–16% carotenoids, mainly β -carotene. In addition crystalline material obtained after extraction with edible oil is also sold.

Astaxanthin

Astaxanthin is biosynthesized by providing both β -ionone rings of β -carotene with hydroxyl- and oxo-moieties at C3 and C4, respectively. The intense dark red xanthophyll, which has no provitamin A activity, plays a role in pigmentation of various animals, conspicuous examples include wild and pen-reared salmon and red crabs, which compulsorily require astaxanthin in their diet. Although recent studies point to superior antioxidant properties compared with β -carotene, astaxanthin applications in nutraceuticals, cosmetics, and food industry are still scarce. The predominant use of the xanthophyll is as a pigmentation source, most notably in aquaculture of salmon and trout. Improved fertility and enhanced immune response are also ascribed to astaxanthin supplementation of the fish diet.

A BCC report released in 2017 estimated the astaxanthin market to be US\$500 million in 2016. Astaxanthin sales account for 25% of the total carotenoid sales, similar to β -carotene. Chemical synthesis supplies the major part of commercial astaxanthin. A minor amount of astaxanthin originates from solvent extraction of crustacean waste or krill.

Microbial astaxanthin production, occupying a small proportion of the market, is based on the chromophyte microalga *Haematococcus pluvialis* and the basidiomycete yeast *X. dendrorhous*, originally named *Phaffia rhodozyma*.

H. pluvialis is grown heterotrophically under low irradiation in closed systems with an excess of organic carbon source such as acetate to achieve a high yield of green biomass, which is thereafter subjected to environmental and nutrient stress to induce aplanospore formation and astaxanthin accumulation. *H. pluvialis* cultures easily fall prey to contaminating microorganisms and

are sensitive to extreme environmental conditions. A selective cultivation environment is not available. Therefore, the second, reddening cultivation stage can only be operated for periods not exceeding 5–6 days if open systems are used. Closed photo-bioreactors in the form of transparent tubes or illuminated stirred tanks might be more efficient systems, but the increased investment and operation costs have to be taken into consideration. *H. pluvialis* biomass is harvested by settling and subsequent centrifugation. After drying and fracturing of the thick cell wall to ensure bioavailability of the enclosed pigment, the biomass contains 1.5–3% of astaxanthin as the 3S, 3S' optical isomer. Several companies with production sites in Hawaii (Mera, Cyanotech), Israel (Algotech), and United States (BioReal AB) offer *H. pluvialis* astaxanthin in the form of a dried algal powder or an oleoresin extract.

X. dendrorhous provides the 3R, 3'R optical isomer of astaxanthin. Mutants selected for increased astaxanthin productivity are cultivated in conventional stirred tank reactors. After harvesting, disintegration, and drying, biomass containing 0.5–1% pigment is marketed by companies like ADM (Ecotone) or Igene (AquaSta) (both in the United States and, since 2013, in Europe). To get about 10 mg per g biomass in shake flasks three steps were performed. First, overexpression of the *X. dendrorhous* genes encoding the enzymes of the biosynthetic pathway. Second, improved precursor supply by an overexpressed 3-hydroxymethyl-3-glutaryl coenzyme A reductase gene. Third, these metabolic engineering steps were performed in a classically selected mutant with a 15-fold production in comparison to the wild-type strain.

Polyunsaturated Fatty Acids

PUFAs are vitamin-like compounds having important structural functions in cell membranes and lipid tissue, and serve as precursors for the biosynthesis of several hormones like leucotrienes, prostaglandins, and thromboxanes. PUFAs are aliphatic monocarboxylic acids with two to six carbon–carbon double bonds in biologically active *cis* configuration within their C18–C24 carbon backbone. The double bonds are separated by two single carbon–carbon bonds resulting in a nonconjugated polyene system. PUFAs are categorized as ω -3 or ω -6, depending on the position of the first double bond on C3 or C6, respectively, when counted from the terminal carbon atom of the fatty acid. They are biosynthesized starting from monounsaturated C18 oleic acid by a series of desaturase and elongase reactions. The genes of most of the PUFA biosynthetic enzymes have been cloned from various organisms. Since mammals lack the ability to introduce double bonds at the ω -3 or ω -6 position of the fatty acid carbon backbone, linoleic acid (18:2, ω -6) and α -linolenic acid (18:3, ω -3) are essential for them. Since the long chain PUFAs arachidonic acid (20:4, ω -6; ARA) and docosahexaenoic acid (22:6, ω -3; DHA) are incorporated in the developing brain, the neuronal tissue and retina of the human fetus studies with supplemented infant formula were performed. Human breast milk contains these PUFAs in tiny (<1%) but significant amounts. The correlation between long chain PUFAs content in the cerebral cortex of breastfed infants and better cognitive and visual function of infants fed with infant formula supplemented with long chain PUFAs suggested that the activity of the enzyme system of elongases and desaturases is suboptimal. Unfortunately, assays for both types of enzymes are not developed yet.

PUFAs have reached a global market size of >1 billion US\$ and are almost exclusively derived from fish oil. In Australia genetic engineering of rape seed has been advanced by Nuseed to produce as much DHA on one hectare as can be extracted from 10,000 fish. Commercial scale microbial processes for the production of DHA and ARA based on natural isolates or classically derived strains are available, which are discussed in some detail here. Attempts to employ molecular engineering techniques in PUFA production have also been published. One example is *S. cerevisiae*, not a natural PUFA producer, that when provided with the appropriate desaturase and elongase genes could perform one or several biosynthetic steps toward eicosapentaenoic acid (20:5, ω -3; EPA) or DHA synthesis starting from the corresponding precursor fatty acids. A series of patent applications from DuPont published in 2004 and 2005 disclosed EPA production in a genetically modified oleogenic yeast, *Yarrowia lipolytica*. In 2013 genetic engineering resulted in about 150 g EPA per kg dry biomass. Analysis of all fatty acids extracted and liberated from glycerol esters more than 50% was found to be EPA.

Docosahexaenoic Acid

DHA, a 22-carbon ω -3 fatty acid with six double bonds, is found in membrane phospholipids of different cell types. For example, in the photosensitive part of the retina DHA accounts for more than 60% of the total fatty acid content. It functions as a signal molecule precursor, and has beneficial effects in prevention of cardiovascular diseases, probably by downregulating intracellular mechanisms leading to expression of proatherogenic genes. Fish, wild catch or from aquaculture, are the most important source of DHA in human diet. Fish cannot synthesize DHA by themselves but marine microorganisms at the lower end of the marine food chain are genuine DHA producers. Aquaculture is often fed with fish oil or fish meal, of which more than 1 million tons and 6 million tons, respectively, were produced in 2005. A negligible proportion of the oil is used for products for the human dietary supplement market. The fish meal industry maintains that fish meal and oil is produced from sustainably managed fish stocks. However, in the general perception, in view of the decade-long over-exploitation of common marine fish resulting in ever-reducing catch size, fish oil is not considered a sustainable source of DHA (and other PUFAs) and microbial alternatives have been developed.

The biomass of the marine microalga *Cryptocodinium cohnii* consists of triglycerides with a high percentage of DHA, which is almost free of other PUFAs. In protracted (200–400 h) lab scale fed-batch fermentations with acetic acid or ethanol as the carbon source, about 100 g L⁻¹ biomass accumulates with a triglyceride content between 30 and 50%. DHA represents about a third of the fatty acids of the triglyceride phase obtained by solvent extraction.

The genera *Schizochytrium*, *Thraustochytrium*, and *Ulkenia*, marine heterotrophic protists classified as labyrinthulomycota, are also preferred sources of microbial DHA. In lab scale fermentations with a *Schizochytrium* sp. strain 60 G L⁻¹ dry cell mass was obtained with a fatty acid content of 70%, of which 37% was DHA. DHA-containing products obtained from protist fermentations is offered by Martek/DSM United States focusing on the human nutrition and aquaculture market, respectively.

Arachidonic Acid

ARA, a 20-carbon ω -6 fatty acid with four double bonds, is a natural component of breast milk, supporting neonatal eye and brain development. Breastfed infants have higher ARA blood levels than formula-fed infants. Infant formulas fortified with ARA and DHA, sold in Europe for more than 10 years, after permission by the Food and Drug Administration (FDA) were first introduced in the United States in 2002 and since then have become increasingly popular.

In contrast to DHA, which can be obtained from fish oil or microbial processes, industrial ARA production solely relies on fermentation processes. First publications on the zygomycete *Mortierella alpina* as a suitable ARA producer appeared in the late 1980s. With the *M. alpina* strains IS-4 or ATCC 32222 lab scale processes were developed affording about 10 G L⁻¹ ARA as triglyceride after 8–10 days fermentation runs in conventional stirred tank reactors. The morphology of the fungal biomass in the reactor is of specific concern. It should appear as small pellets with a diameter of 1–2 mm to allow for sufficient mass transfer and to keep the broth viscosity at an acceptable level. About 70 g L⁻¹ biomass and containing 18 g L⁻¹ ARA are reported. After fermentation, the *M. alpina* mycelium is harvested by centrifugation or filtration, dried, and solvent-extracted. Alternatively, the mycelium is homogenized as an aqueous suspension and extracted with a water-immiscible organic solvent.

Fungal ARA is produced and marketed as Arasco by Martek /DSM (United States). In 2004, Cargill (United States), a leading supplier of agriculture products and food ingredients, entered into a joint venture with Wuhan Alking Bioengineering Co. Ltd. (Hubei Province, China), an ARA producer serving the Chinese infant formula business. Suntory, a leading Japanese non-alcoholic beverage manufacturer and a pioneer in microbial PUFA production, provides a fungal ARA oil under the trade name Suntga40S. A small volume but premium price application of ARA enriched oil is its use as the basis for cosmetic creams.

Water-Soluble Vitamins

Riboflavin

Riboflavin is the common name of 7,8-dimethyl-10-(D-1'-ribityl)isoalloxazine, also known as vitamin B2, colorant E101, lactoflavin, lactochrome, or ovoflavin. The latter names referring to the source the vitamin was derived from. The compound is naturally synthesized by plants and most microorganisms, but not by higher eukaryotes. Starting from GTP and ribulose 5-phosphate the riboflavin biosynthesis pathways of fungi and bacteria are similar, albeit the order of two consecutive biosynthetic steps, the reductase and deaminase reactions, is inverted. The genes encoding the riboflavin biosynthetic enzymes are well conserved among bacteria and fungi. Vitamin B2 has key functions in energy metabolism, maintenance of healthy skin and muscles, support of immune and nervous system, and promotion of cell growth and division. Riboflavin is the precursor for the coenzymes FMN (flavin mononucleotide) and flavin adenine dinucleotide (FAD), which are both important electron carriers in biological redox reactions. Furthermore, the two flavo-coenzymes participate in nonredox phenomena like bioluminescence, light sensing, phototropism, DNA protection against UV, and in resetting of the circadian clock. Light sensitivity and poor resorption makes riboflavin deficiency recurrent, as suggested by worldwide surveys on nutritional status, and supplementation is often recommended. Overdosing due to dietary supplementation does not occur owing to the direct excretion of riboflavin in the urine. In industrialized countries processed food is often fortified by the use of riboflavin as a colorant or vitamin supplement. The main application (70%) of commercial riboflavin is in animal feed, since productive livestock, especially poultry and pigs, show growth retardation and diarrhea in case of riboflavin deficiency. According to a report by SRIC, a consulting company in Menlo Park (California), in 2005 the need for industrially produced riboflavin was estimated at 6500–7000 t year⁻¹.

Industrial riboflavin production, a domain of the chemical industry for a long time, followed a six- to eight-step route starting from 3,4-xylydine, barbituric acid, and D-ribose. The latter is provided by the chemical conversion of glucose or more recently by fermentation from glucose using transketolase-deficient *Bacillus* sp. production strains. The first commercial single-stage riboflavin fermentations came up in the 1940s employing *Clostridium acetobutylicum* and, more efficient, the fungi *Eremothecium ashbyi* and *A. gossypii*. However, all three companies manufacturing riboflavin by fermentation in 1965 shut down their production plants in 1968 as their production processes were competitively disadvantaged to chemical processes. Nevertheless, riboflavin biosynthesis meanwhile has become the paradigm for environmentally superior white biotechnology replacing chemical production processes. Although Merck (Germany) resumed fermentation using *A. gossypii* in 1974, the success story started with an *A. gossypii* production plant by BASF (Germany) in 1990. The market share of riboflavin bioprocesses thereafter increased from 5% in 1990 to 75% in 2002, of which initially, the two naturally vitamin B2-overproducing fungi *A. gossypii* and *Candida famata*, and later, genetically modified strains of the bacterium *B. subtilis* were used. However, *C. famata* is not employed any longer and chemical riboflavin production came to an end, leaving only *A. gossypii*- and *B. subtilis*-based production methods. Both processes are the outcome of classical strain improvement, genetic engineering, and process optimization.

The wild-type strain of the filamentous fungus *A. gossypii*, originally isolated as a severe but today negligible cotton pathogen, produces 2 mg riboflavin per gram of biomass, possibly for UV-light-protection of its spores. Adjustment of process parameters

allows a production above 100 mg G⁻¹ biomass even by wild-type strains. However, at the industrial scale the performance of *A. gossypii* production strains was increased by analysis of the pathway from the very first enzyme, an extracellular lipase hydrolyzing plant triglycerides serving as the carbon source, to the carrier systems transporting the vitamin into the vacuole or extracellular space. Within a decade the production process was improved by (1) optimization of culture conditions, that is, different medium compositions for growth and production phases, (2) selection of antimetabolite-resistant mutants, that is, using inhibitors against key enzymes limiting reaction velocity like isocitrate lyase, (3) overexpression of RIB genes, that is, integration of additional copies of RIB3 encoding the enzyme converting ribulose-5-phosphate into 3,4-dihydroxy-2-butanone-4-phosphate (DHBP), and (4) decreasing the flux to unwanted side products by disruption of genes, for example SHM2, encoding cytosolic serine hydroxymethyl transferase that converts glycine, a precursor of riboflavin, into L-serine. Metabolic design of *A. gossypii* is possible by self-cloning, gaining stable genomic integrations targetable by homologous recombination. Large-scale fermentation of *A. gossypii* is advantageous because extracellular hydrolases allow high loads of osmotically inactive carbon sources like triglycerides removing the need for controlled carbon feeding and autolysis of the vitamin-accumulating cells can be controlled by a temperature shift.

B. subtilis, a soil bacterium, strains of which are traditionally used in food preparation in Asia, for example, for the soy bean fermentation product natto, is capable of synthesizing industrially relevant amounts of vitamin B2 only after genetic engineering. In wild-type strains, riboflavin biosynthesis is minimized to the physiological needs of the bacterium by a tight riboswitch transcriptional attenuation mechanism of the rib genes. A suitable *B. subtilis* host strain was obtained by resistance screening against three purine analogues (8-azaguanine (S1), decoyinine (S2), and methionine sulfoxide (S3)) (Fig. 1), yielding mutants with a deregulated purine synthesis pathway that provided an enhanced availability of the riboflavin precursor GTP. Starting from a purine-analogue resistant strain, a mutant resistant against the riboflavin analogue roseoflavin was selected (S4). Later it turned out that flavo-coenzyme-mediated attenuation of rib gene expression was abolished in this mutant, which expressed a flavokinase with drastically reduced activity causing reduced intracellular FMN and FAD levels. A defect in adenylosuccinate synthetase causing a block in the flux from inosine monophosphate (IMP) to adenosine monophosphate (AMP) was advantageous for purin precursor production, but the resulting adenine auxotrophy was detrimental to riboflavin overproducing strains. Overexpression of the *B. subtilis* rib operon comprising all relevant rib genes (ribA, ribG, ribH, ribB) by use of a phage promoter, multicopy genomic insertion of the engineered operon, and by providing an additional expression cassette for ribA encoding a bifunctional enzyme catalyzing two entrance reactions of the converging riboflavin pathway led to a production strain fit for industrial application (GE1

Fig. 1 Important steps in manipulation of biochemical and regulatory pathways to obtain riboflavin overproduction by *Bacillus subtilis*. Simplified scheme of metabolic steps (arrows) and relevant regulations (broken lines) from the main carbon source glucose to the targeted product riboflavin. ⊕ and ⊖ mark increased or decreased fluxes or activities, as appropriate, all with a positive effect on riboflavin production. Labels depict metabolic steps or regulations affected in antimetabolite selected mutants (S) or genetically engineered strains (GE). See text for details. gluc-6p, glucose-6-phosphate; ribu-5p, ribulose-5-phosphate; IMP, inosine monophosphate; AMP, adenosine monophosphate; XMP, xanthosine monophosphate; GMP, guanosine monophosphate; GTP, guanosine triphosphate; DHBP, 3,4-dihydroxy-2-butanone 4-phosphate; DRL, 6,7-dimethyl-8-ribityllumazine; FMN, flavin mononucleotide; FAD, flavin adenine dinucleotide.

and GE2). Meanwhile, a new generation of marker-free, self-cloned *B. subtilis* production strains have been constructed, achieving high production performance with a single copy of a precisely engineered rib operon. A mutation induced in the *tkl* gene reduces but not completely abolishes the enzymatic activity of the encoded transketolase enzyme, thus allowing higher intracellular concentrations of the intermediate ribulose-5-phosphate.

Rational design of high performance *A. gossypii* or *B. subtilis* production strains to channel a major metabolic flux toward the target compound and to prevent drainage of resources into side or waste products became possible only after a detailed understanding of riboflavin biosynthesis was available. Construction of the strains depended on a filled tool box for mutant screening, DNA synthesis, and recombination. PCR technologies and synthetic genes including their regulatory DNA components facilitated precision engineering to avoid surplus DNA and antibiotic markers in the final production strains.

During the fermentation process, riboflavin is exported from the cells into the medium and crystallizes in the fermentation broth due to its low solubility in neutral aqueous media. In *A. gossypii* additionally a transport into the vacuoles occurs. The long, needle-shaped crystals can easily be recovered from the fermentation broth and separated from the biomass by several rounds of centrifugation and resuspension in water. Microbial riboflavin production at an industrial scale turned out to be both cost-effective and environmentally friendly compared with conventional chemical synthesis: carbon dioxide emissions and use of nonrenewable resources were reduced by 80% each and water emissions by 66%. Fermentation products for food and pharmaceutical applications offer a higher purity as aniline and other impurities found with chemical synthesis are absent. For feed applications, products with reduced purity are accepted since the impurities consist of residual biomass with additional nutritional value.

Major riboflavin producers are DSM Nutritional Products (Switzerland) and Hubei Guangji (Hubei Province, China), both using genetically engineered *B. subtilis* production strains, and BASF (first in Germany but now in South Korea), employing genetically engineered *A. gossypii*.

In conclusion, the supersession of chemical vitamin B2 synthesis by fermentation aided by classical strain improvement and genetic engineering is an encouraging example of the potentialities of white biotechnology.

Cobalamin

Industrially produced vitamin B12, used as a nutritional supplement, by definition is an artificial cobalamin compound with a cyano ligand derived from natural cobalamins like adenosyl-, methyl-, or hydroxy cobalamins. However, the term vitamin B12 is often also used for the natural cobalamins. Cobalamins are the chemically most complex of all vitamins, consisting of a 15-membered, planar corrin ring with a central cobalt ion (hence the name), a dimethylbenzimidazole group as the lower ligand, and an adenosyl-, methyl-, hydroxy-, or cyano group as the upper ligand, giving rise to the aforementioned four cobalamin compounds. Vitamin B12 is an essential nutrient for plants and animals, since only some bacteria and archaea can synthesize it de novo. Among enteric bacteria two pathways, an aerobic pathway as in *Pseudomonas denitrificans* and an anaerobic pathway as in *Propionibacteria* or *Salmonella typhimurium*, have been identified for the initial corrin ring formation and the insertion of cobalt. In the prehistoric environment where the atmosphere lacked oxygen today's corrinoid enzyme originated enabling anaerobic metabolism in which carbon dioxide is reduced to methane. With increasing oxygen in the atmosphere and the evolution of porphyrin compounds like heme or chlorophyll, cobalamin-dependent enzymes gained function in other methyl-dependent reactions. In human physiology, adenosylcobalamin and methylcobalamin are important coenzymes linked to the formation of blood, fat metabolism, and the normal functioning of the nervous system and the brain. Vitamin B12 deficiency causes, among others, several forms of anemia, and has been long used as a diagnostic tool. Recent surveys point to a high proportion of inadequate intake, even in industrial countries, and the need of nutritional supplementation, especially for vegans and elderly people.

Industrial vitamin B12 production has never been carried out by the complex chemical synthesis route, comprising over 70 steps. Instead, cobalamins initially extracted from feces, sapropel, or *Streptomyces* sp. cultures used for antibiotic production were exclusively manufactured by fermentation, employing species of *Bacillus*, *Methanobacterium*, *Propionibacterium*, or *Pseudomonas*. The global production in the range of less than 100 t year⁻¹ is low, but a selling price of more than a thousand euros kg⁻¹ drew several Chinese producers (e.g. Hebei Huarong Pharmaceutical Co., Ltd., NCPC Victor Co., Ltd., and Hebei Yuxing Bio-Engineering Co., Ltd.) into the market that was dominated by the French Sanofi-Aventis. As a result, the market is currently characterized by severe production overcapacities and concomitant price pressure. Nowadays, the bacterium *P. denitrificans* is almost exclusively used as the production organism. Investigations of the vitamin B12 biosynthesis pathway in *P. denitrificans* and cloning of the 22 cob genes of the organism allowed researchers at Rhone Poulenc to construct genetically engineered production strains presumably providing a technological advantage in terms of productivity and yield on raw materials over strains solely obtained by classical strain improvement. Glycine betaine present in significant amounts in sugar beet molasses or the biosynthetic precursor choline chloride are indispensable for high productivity. The fermentation medium also provides a cobalt salt and dimethylbenzimidazole as components of the cobalamin molecule. During the 7-day fermentation run, adenosylcobalamin is predominantly secreted from the biomass and accumulates in the fermentation broth in milligram amounts. The downstream steps comprise filtration, cyanide treatment, chromatography, extraction, and crystallization yielding vitamin B12 in high purity. However, optimization of recombinant B12 synthesis is still under investigation, wherein the most likely host is *P. denitrificans*. A key limitation is the absence of export systems.

L-Ascorbic Acid

Vitamin C probably has the most interesting history of all vitamins. The famous Ebers papyrus from 1550 BCE already describes the avitaminose symptoms of scurvy, a formerly common disease among mariners and explorers. Scurvy resulting from a lack of vitamin C in the human diet leads to collagen instability causing inter alia loss of teeth and bleeding of all mucous membranes. Vitamin C is chemically defined as L-ascorbic acid, a weak six-carbon sugar acid with a pentagonal ring structure. The exocyclic C5 has L-configuration, and in higher organisms only the L-enantiomer of ascorbic acid is biologically active. The pivotal functions making vitamin C essential are both the high antioxidant capacity and cofactor effects in the synthesis of collagen, carnitine, and hormones like adrenaline. For use as a food additive, several E numbers represent different chemical forms of vitamin C, that is, E300 (free ascorbic acid), E301–303 (ascorbate salts of sodium, calcium or potassium, respectively), E304 (fatty esters), and E315 (erythorbic acid, a stereoisomer). Starting from D-glucose, L-ascorbic acid biosynthesis follows different routes in plants and animals. L-Galactono- γ -lactone, the ultimate precursor of the plant pathway, is reached via an inversion of the D-glucose carbon skeleton. In animals, L-gulono- γ -lactone is obtained by three epimerization reactions. All plants and most animal species are prototrophic for vitamin C. Nevertheless, humans, higher primates, guinea pigs, and a small number of other animals require vitamin C supplementation of their diet due to a defective GULO gene encoding L-gulono-1,4-lactone oxidase, the last enzyme in the synthesis pathway in animals. Fungi of the genera *Zygomycetes*, *Ascomycetes*, or *Basidiomycetes* synthesize D-erythroascorbate, a C5 analogue of ascorbate, from D-arabinose via an inversion pathway.

L-Ascorbic acid and its chemical derivatives are by far the most bulk produced vitamins with more than 100,000 t year⁻¹. Chinese manufacturers entering the vitamin C market in the early 1990s caused a ruinous competition. DSM Nutritional Products Ltd. from Switzerland (formerly Roche Vitamins), the sole Western producer, positioned itself in the premium segment of the market. Chinese companies like Weisheng Pharma, North China Pharmaceutical Company (both in Hebei Province), and Jiangshan Pharmaceutical Co. (Jiangsu Province) became the leading producers for the bulk market. In contrast to other vitamins, feed applications of L-ascorbic acid account for only 10%, whereas the main uses are in the pharmaceutical industry (50%), food (25%), and beverages (15%). Pharmaceutical applications include stimulation of collagen synthesis (especially cosmetic products) and high antioxidant capacity, used for the reported health benefits in the prevention of flu, heart diseases, and cancer, as well as an antidote for poisoning. The food and beverage industry predominantly exploits the antioxidant capacity of L-ascorbic acid to extend durability, prevent discoloration, and to protect flavor and nutrient contents of their products.

Industrial production of vitamin C initially started by extraction from fruit. The first chemical process based on L-xylosone was carried out in 1933. In 1934, the famous Reichstein–Grüssner process was published. The process starts with a chemical hydrogenation of D-glucose to D-sorbitol, followed by the oxidation of the sugar alcohol to L-sorbose using *Gluconobacter* sp. strains as biocatalysts. The subsequent chemical steps including acetonization, oxidation, deacetonization, and rearrangement of the oxidation product 2-keto-L-gluconic acid (2KGA) deliver L-ascorbic acid. Although more than 70 years old, the technique with a typical yield of above 50% on starting glucose is still in use, a testimony to the fact that the advantages of long-term process optimization still allows classical methods to compete with more modern microbial-based production methods.

Chinese vitamin C manufacturers produce 2KGA by a two-stage microbial process developed in China in the late 1960s and 1970s. As in the Reichstein process, L-sorbose is provided by *Gluconobacter* sp. oxidation of D-sorbitol (first stage). In a second fermentation step, replacing the chemical oxidation steps, 2KGA is obtained via L-sorbose employing *Ketogulonigenium* sp. strains, in Chinese literature frequently referred to as *Gluconobacter oxidans*. For efficient oxidation co-cultivation with a helper strain, for example, *Bacillus megaterium*, is mandatory but the underlying molecular mechanism is still unclear. The execution of the process in two steps is necessary to prevent *Ketogulonigenium* sp. from metabolizing D-sorbitol, which would lead to the production of unwanted D-glucose and its oxidation products. Finally, as in the Reichstein process, 2KGA is chemically converted to L-ascorbic acid. The two-stage process can achieve up to 130 g L⁻¹ 2KGA with a yield of above 80% on D-sorbitol. The reduced number of process steps compared to the Reichstein process, less process complexity, lower investment costs, less energy demand, and lower chemical consumption make the two-stage process advantageous.

G. oxidans alone is able to oxidize D-sorbitol to 2KGA, however, even processes based on genetically engineered *G. oxidans* strains cannot match the space–time yield of mixed culture processes.

Alternative microbial routes to 2KGA synthesis starting from D-glucose via 2,5-diketo-D-gluconate have been developed employing *Erwinia* sp. and *Corynebacterium* sp. in a two-step tandem process or by using genetically engineered *Erwinia* sp. expressing a gene for a *Corynebacterium* 2,5-diketo-reductase. These processes have yet to make it to industrial realization.

In summary, all vitamin C bioprocesses developed to an industrial stage so far result in the formation of the precursor compound 2KGA, requiring a cost-driving chemical rearrangement step to achieve the final product. Obviously, numerous attempts have been made to design microbial synthesis routes that result in direct synthesis of vitamin C. One approach tried to utilize the biosynthetic capacity of baker's yeast to synthesize the five-carbon vitamin C analogue D-erythroascorbic acid. Indeed, genetically engineered *S. cerevisiae* strains produced minor amounts of L-ascorbic acid starting from L-galactose, which should be supplied from a combination of epimerase and isomerase reactions starting from the Reichstein intermediate L-sorbose. In a second approach, microalgae synthesizing vitamin C according to the plant biosynthetic pathway via galactono- γ -lactone yielded up to 2 g L⁻¹, the synthesized vitamin mainly associated with the biomass. Although cheap D-glucose was the fermentation substrate, the reported low productivity renders a commercial application of the microalgae system rather unlikely. However, a promising direct route to vitamin C might have been opened by the discovery of dehydrogenases present in *Ketogulonigenium* sp. and *Gluconobacter* sp. that convert L-sorbose, the partially oxidized biosynthetic intermediate of microbial 2KGA processes, into vitamin C.

Production Efforts for Other Vitamins

R-Pantothenic Acid

Efforts on developing microbial production processes for water-soluble vitamins are not limited to the vitamins B2, B12, and C, as discussed in detail in the previous sections. The next vitamin to be industrially produced by a fermentation process might be R-pantothenic acid, also known as vitamin B5. R-Pantothenic acid plays a vital role for a multitude of metabolic processes in all living cells, serving among others as a building block for the biosynthesis of coenzyme A. Pantothenate is synthesized by bacteria, fungi, and plants, but not by mammals, including livestock and humans. The current worldwide demand of more than 5000 t is produced by chemical synthesis involving a racemic resolution step that can be carried out biocatalytically at the industrial stage.

Biosynthesis of pantothenic acid starting from the common metabolic intermediates α -ketoisovalerate and aspartate is well understood. The products of the panB and panE genes are involved in the conversion of α -ketoisovalerate to R-pantothenate. The panD gene product is a pyruvoyl-dependent decarboxylase converting aspartate to β -alanine. The ATP-dependent panC gene product combines the two pantothenic acid precursors into the final product. Biotechnical approaches based on genetically modified *E. coli*, *Corynebacterium glutamicum*, and *B. subtilis* have been reported. The *E. coli* process developed by Takeda Chemical Industries Ltd. (Japan) delivers a respectable 66 G L⁻¹ of R-pantothenic acid in a 72 h fermentation run, but requires β -alanine as a co-substrate. The fact that in the *E. coli* process 40% of the molecular mass of pantothenic acid is not provided by the basic carbohydrate fermentation substrate, but originates from the processed chemical β -alanine should not be without disadvantageous economic consequences. The *B. subtilis* procedure developed by Omnigene Inc. (United States) shows an even higher productivity with 86 G L⁻¹ R-pantothenic acid accumulating within 48 h of fermentation. Interestingly, sufficient β -alanine is provided endogenously in this process superseding exogenous β -alanine supply.

D-Biotin

Biotin, also known as vitamin H or B7, is an important catalyst in essential metabolic conversions like gluconeogenesis and fatty acid synthesis. Usually produced in excess by intestinal bacteria, biotin is mainly of cosmetical interest as it strengthens hair and nails. Significant efforts have been made to design a microbial process for D-biotin, which is currently produced in a complex multistep chemical process. Tanabe Seiyaku Ltd. (Japan) in the early 1990s developed a process based on genetically modified bacterium *Serratia marcescens* affording 540 mg L⁻¹ of D-biotin during 144 h of fermentation. Biotin-overproducing recombinant *Kurthia* sp. and *B. subtilis* were developed at Nippon Roche (Japan) and Omnigene Inc. (United States), respectively.

Biotin biosynthesis involves pimeloyl-CoA, a derivative of the seven-carbon dicarboxylic pimelic acid. In *B. subtilis* pimelic acid and alanine are converted to dethiobiotin via four biosynthetic steps catalyzed by the gene products of bioW, bioF, bioA, and bioD. The subsequent BioB-catalyzed conversion of dethiobiotin to biotin involves the formation of an adenosyl radical. Interestingly, one of the two iron-sulfur clusters of BioB is probably the immediate sulfur source of biotin. This remarkable BioB reaction attracted much scientific attention, but is still incompletely understood. Solving the BioB enigma is regarded as a key milestone toward developing a competitive microbial biotin production process.

Vitamins B1 B6, and Folic Acid

Serious efforts have been devoted to the development of microbial production processes for vitamins B1 (thiamine), B6 (pyridoxol), and folic acid based on various bacterial host strains including *E. coli*, *B. subtilis*, and *Rhizobium meliloti*. In all cases, genetic engineering approaches were applied to deregulate and overexpress the genes known to be involved in the respective metabolic pathways. Although the engineered strains produced significantly higher levels of the vitamins compared with their wild-type ancestors, their productivities were far too low for commercial application. As in the case of biotin, it seems that an incomplete understanding of the biochemical fundamentals is a serious impediment for the development of competitive fermentation processes for these vitamins.

Conclusions and Outlook

All microbial processes discussed in this article are part of white biotechnology, which in contrast to red biotechnology (medical sector) and green biotechnology (genetically engineered crops) deals with industrial application of biological systems to produce chemicals, materials, and energy. Several recent studies estimate the current share of biotechnical processes in various chemical productions to increase from about 5–20% by 2010. Fine chemicals with high functionality and a typical annual worldwide demand below 10,000 t year⁻¹, for example, vitamins, are expected to be a future market for bioprocesses, with an estimated fivefold increase in their world market value to around US\$250 billion within the next 10–20 years. By 2020, it is anticipated that 20% of today's chemically manufactured fine chemicals, bulk products and polymers (production greater than 10,000 t year⁻¹) will be biotechnically produced.

Important products of white biotechnical are food ingredients, vitamins, biocolorants, solvents, degradable bioplastics, and biofuels, in which typically microorganisms or isolated enzymes quickly catalyze even crucial chiral products with a remarkable specificity. This goes along with a reduction in emissions, water usage, energy demand, and waste. White biotechnical applications for animal or plant cells are also conceivable, but microorganisms are usually preferred due to their faster growth, easier handling, and often relatively easily modifiable genetic material. As in vitamin B2 production, coexistence of an obviously faster cultivation process with a bacterium and a process applying a more slowly growing filamentous fungus is possible. Hence other advantages like substrate quality or final product concentration have a significant impact. To develop a new bioprocess for vitamin synthesis, in principle two general strategies are feasible, albeit a successful production strain is often the result of both approaches. The first strategy starts with screening for natural overproducers, that is, species already producing the compound of interest in considerable amounts. The yield is then consecutively improved by several rounds of mutagenesis (by chemicals or UV radiation) and selection, for which minimal knowledge about the metabolism and genetic organization of the microorganism employed is sufficient. On the contrary, the second tactic, namely targeted deregulation of metabolism by application of recombinant DNA techniques, is only appropriate for thoroughly studied organisms. Apart from the need for sufficiently effective means of genetic manipulation, pathway elucidation is an important prerequisite for this approach. The economic success story of commercial riboflavin production by *B. subtilis* is a proof of concept of how satisfactorily the second strategy can work. Moreover, innovative methods like altering metabolic flux and metabolic control studies, as well as transcriptome analyses, advanced screening techniques (such as using novel antimetabolites), and computer simulations further support the re-education of long-time microbial workhorses into production strains of new compounds. However, even for genetically well-known organisms, still some fundamental dilemmas exist. First, elucidation of both the synthesis pathway and the transport processes of product, intermediates, and co-metabolites as yet needs time-consuming and costly basic or pure research. Publication of genomes also is only the beginning of protracted discovery of the function of numerous unknown open reading frames. For instance the genomes of *B. subtilis* and *A. gossypii* have been publicly available for years but only riboflavin importer genes of *B. subtilis* and *S. cerevisiae* were identified recently. Kinetic studies have shown that in *A. gossypii* at least an uptake and a separate export system plus a proton gradient-driven system in the vacuolar membrane must exist. Moreover, metabolic enhancement of several key enzymes in compound synthesis and transport is significantly impeded due to the lack of direct enzyme activity assays, either because the enzyme of interest is membrane-bound or owing to a shortage of sufficient test-substrate availability. As described above for vitamins B12 and B2 production, actual availability for the microbial cell is the crux of highly efficient fermentation, wherein choice of feedstock as well as supplementation with additional precursors and regulative compounds fundamentally affect the financial survival of the microbial fabrication technique versus chemistry. Likewise, as for vitamin C production with yeasts and microbial vitamin B5 synthesis, supplementation costs often render a bioprocess uneconomical until genetic engineering overcomes its limitations or changes in the general framework, such as decreasing prices for the supplements needed or increasing production costs of competing chemical synthesis, become effective. However, some microbial production concepts have no chance of success because of the intrinsic characteristics of the available or preferred microorganisms. An example is the production of fat-soluble vitamins, which not only needs precursors but also a storage depot within the cell, hence excluding bacteria in the production process. Nevertheless, microorganisms have already proven to exhibit an outstanding versatility in metabolism, although as yet only a small fraction of existing species has been discovered and classified. Screening for new isolated strains from seawater, soil, or extreme habitats is thus still a common method in the development of novel bioprocesses, in particular for delicate challenges like synthesizing PUFAs. Moreover, unveiling of vitamin-like functions of novel compounds is expected since, additional to the almost six thousand bioactive metabolites described so far in the literature, the potential industrial capacity of marine microorganisms, to name only one group, is estimated by hundreds of compounds having industrially interesting novel structures and properties.

Given the undisputed beneficial effects of an adequate vitamin supply in food and feed, the question raised now is how this demand can be satisfied. Since fossil and natural resources (e.g., fish oil) are depleting, in the long term a transition from a fossil-based to a bio-based economy and society is needed. Apart from microbial production processes, green chemistry offers a short-term cost-efficient perspective, in which plant products, such as oils or sugars, are microbially converted *inter alia* into vitamins. A more direct and long-term approach is the metabolic engineering of the plants themselves to increase their nutritional value. A prime example of this strategy is 'golden rice' enriched in provitamin A, manufactured since the late 1990s.

Despite all advantages, there are still many factors that impair the transformation from conventional to biotechnical industry. Many reports conclude that the main barrier in the industry is because of conservative thinking, summing up the lack of knowledge both on bioprocess alternatives and on environmentally crucial steps of the current processes in plant management, as well as a lack of suppliers and advertising of biotechnical intermediate or end products. Moreover, international competition often allows little room and little demand for investments in new technology. However, since fossil resources are diminishing, pollution control becoming increasingly expensive, and customers asking for environmentally friendly products, white biotechnical is boosted. Thus Europe and the United States, the current market leaders, are anticipated to increase state-of-the-art research and industrial implementation of new bioprocesses. Although fermentation processes are already being applied in the synthesis of several vitamins and vitamin-like compounds, often the final aim is the total replacement of chemical synthesis by feasible and economic biocatalytical systems using cost-efficient and sustainable raw materials. It remains to be seen in the following years, whether the above described biotechniques are sufficiently efficient to compete with chemical synthesis, imminent or existing combined methods, or upcoming genetically engineered vitamin-enriched crops.

Glossary

Activated sludge (AS) An aerobic treatment process with suspended biomass waste.

Biological oxygen demand (BOD) A bulk measurement of the concentration of oxygen consumed during the biodegradation of organic compounds in the wastewater; may be reported after a 5-day measurement period (so-called BOD₅) or tested on filtered wastewater (so-called soluble or sBOD).

Chemical oxygen demand (COD) A measurement of the overall oxygen concentration utilized to chemically oxidize all of the organic compounds in a wastewater sample.

Hydraulic residence time (HRT) The average retention time of water in a treatment system.

Membrane bioreactor (MBR) Coupling ultrafiltration or microfiltration membranes with biological treatment reactors (typically an AS reactor) to retain biomass.

Moving bed biofilm reactor (MBBR) A hybrid treatment reactor that is typically aerobic.

Organic loading rate (OLR) The rate at which organics are loaded to a treatment reactor. It is usually calculated as the concentration of organics in the wastewater (typically in kg COD or BOD m⁻³) multiplied by the flowrate applied to the treatment reactor (in m³ day⁻¹) divided by the reactor volume (in m³) or sometimes the surface area (in m²).

Rotating biological contactor (RBC) An aerobic treatment system with biomass attached on rotating disks.

Sequencing batch biofilm reactor (SBBR) A SBR to which solid media has been added to allow attached biomass to accumulate in the treatment reactor.

Solids residence time (SRT) Average time that the biomass is retained in the biotreatment system.

Surface area loading rates (SALR) Typically reported for organics loading onto filters or wetland treatment systems.

Suspended solids (SS) Solids larger than ~1 μm in size; can include organic solids and bacteria.

Total Kjeldahl nitrogen (TKN) Includes ammonia-N and organic-N.

Total phosphorus (TP) Includes phosphate-P, organic P, and so on.

Upflow anaerobic sludge blanket (UASB) A common anaerobic treatment reactor.

Abbreviations

AF	anaerobic filters
AMW	apparent molecular weights
AS	activated sludge
ASB	aerated stabilization basins
BAFs	biological aerated filters
BES	bioelectrochemical systems
BOD	biological oxygen demand
COD	chemical oxygen demand
CSTR	completely stirred tank reactor
DGGE	denaturing gradient gel electrophoresis
EGSB	expanded granular sludge bed

[☆]*Change History:* June 2016. A.R. Bielefeldt added a new section on electricity production from industrial wastewater; updated Table 2; added new references into Tables 3 and 4; and modified the "Abstract" and "Conclusions" sections based on the new section that was added.

EPA	environmental protection agency
FAME	fatty acid methyl ester
FB	fluidized bed
FC	fecal coliforms
FISH	fluorescence in situ hybridization
FWS	free water surface
GSS	gas–solids separators
HRT	hydraulic residence time
IC	internal circulation
IFFAS	integrated fixed film activated sludge
JRLs	jet loop reactors
MBBR	moving bed biofilm reactor
MBR	membrane bioreactors
METs	microbial electrochemical technologies
MF	microfiltration
MFC	microbial fuel cell
NOB	nitrite-oxidizing bacteria
PCR	polymerase chain reaction
RBC	rotating biological contactor
SALR	surface area loading rates
SBBR	sequencing batch biofilm reactor
SBR	sequencing batch reactor
SRT	solids residence time
SSF	subsurface flow
TOC	total organic carbon
TRI	toxics release inventory
UASB	upflow anaerobic sludge blanket
UF	ultrafiltration
WET	whole effluent toxicity

Defining Statement

An overview of microbiological methods to treat industrial wastewaters is provided. The range of characteristics of common industrial wastewaters is provided. Commonly used aerobic, anaerobic, coupled, and wetland treatment processes are described. Case studies from full-scale systems are highlighted, along with key emerging results from laboratory and pilot-scale studies.

Biological Treatment of Industrial Wastewater

Industrial wastewaters are generated from a wide variety of sources and have a broad diversity of chemical properties and constituents. In the United States, the Federal Environmental Protection Agency (EPA) has developed wastewater discharge standards for over 60 industries (40 CFR Chapter 1, Subchapter N Effluent Guidelines and Standards). There are also pretreatment standards that regulate the quality of wastewater discharged from industries into public sewers under the National Pretreatment Program (EPA-833-B-98-002). To achieve the wastewater characteristics required by the standards, more industries are treating their wastewater on-site by a variety of processes. Most of these processes are aimed at reducing the concentrations of total organics, total solids, and/or specific chemicals down to acceptable concentrations. Many treatment processes can be quite expensive, and biological processes are considered to be cost-effective alternatives when the primary contaminants of concern are biodegradable organics or nitrogen compounds. Treatment designs are continually evolving to provide greater treatment efficiency. Microbial methods that are used to treat industrial wastewaters must be more robust than traditional municipal wastewater treatment processes due to the greater variability in flow rates and chemical characteristics, and the potential presence of toxic or inhibitory compounds. More innovative approaches to achieve treatment objectives include coupling anaerobic and aerobic processes, and coupling biological and chemical treatment processes. Molecular methods are beginning to be used to characterize the microorganisms present in the wastewater and present in treatment reactors. Improved capabilities to extract energy and even electricity from industrial wastewater are evolving.

Characteristics of Industrial Wastewater

Unlike municipal wastewater, the wastewater generated from different industrial activities has widely varying composition. Even within a single type of industry, the specific processes and chemicals used to produce similar products can differ resulting in

Table 1 Examples of typical industrial wastewater characteristics

Wastewater type	Average pH range	Suspended solids (mg L ⁻¹)	BOD ₅ (mg L ⁻¹)	COD (mg L ⁻¹)	TKN (mg N L ⁻¹)	Total P (mg L ⁻¹)	Salt (g L ⁻¹)
Brewery	3.3–7.6	500–3000	1400–2000	815–12,500	14–171	16–124	
Dairy milk–cheese plants	5.2–11.3	350–1082	709–10,000	189–20,000	14–450	37–78	0.5
Dairy parlor	2–11	100–300	166–477	470–820	25–45	17–21	0.05–0.7
Dying	8.2–12	56–70	140–840	70–3200	27–42	5–7	
Food pickling	2.6–3	40–110	7000–8000	20,000–22,000	4–6	22–25	30–150
Metal working fluids	9		1500–11,400	5300–40,000	160–440	28–77	
Pulp and paper	6.6–10	21–1120	77–1150	100–3500	1–3	1–3	~0.05
Tannery	8–11	2070–4320	1000–7200	3500–13,500	250–1000	4–107	6–40
Textile mills	4.5–10.1	20–210	700–1650	1900–100,000	14–72	1–18	0.5–0.9
Winery	3.9–5.5	170–1400	210–8000	320–27,200	21–64	16–66	0.1–1
Municipal	6–8	100–350	110–400	250–1000	20–85	4–15	<0.5

significant changes in wastewater characteristics over time. For example, the wastewater stream at a brewery is actually made up of a combination of wastes from different processes, including waste from malting, brewing, fermenting, yeast drying, conditioning, and packaging. Similarly, textile mill effluent may be a combination of bleaching, fiber dyeing, yarn dyeing, and rinsing wastewater streams. A sample of reported wastewater composition is provided in Table 1.

Industrial wastewaters may be caustic, with extreme pH values of less than 2 or greater than 12; these extreme pH values may result from different cleaning agents that are used. Without buffering to more neutral conditions, these extreme pH values would be inhibitory to microorganisms. Some industrial wastewaters contain extremely high concentrations of organic compounds (measured as biological oxygen demand (BOD) or chemical oxygen demand (COD)); these organic concentrations may be more than ten times the concentrations in municipal wastewater. High salt concentrations are also present in some types of industrial wastewaters. Nutrient limitations are a potential problem for biological treatment of some industrial waste streams, including nitrogen (N) limitation in brewery wastewater, phosphorus (P) limitation in pulp and paper wastes including Kraft pulp and cellulose production wastewaters, and N and P limitation in winery and pickling wastewaters. In other cases, a significant excess of nutrients may be present, such as in the case of pectin factory wastewaters with 1280–2990 mg L⁻¹ nitrate-N and COD/N ratios of 7 to 12:1.

In addition to bulk chemical constituents, many industrial wastewaters also contain specific organic and inorganic compounds that are toxic. For example, tannery wastewaters may contain 50–100 mg L⁻¹ chromium. The US Environmental Protection Agency tracks the industrial use, treatment, and release of more than 600 chemicals via the Toxics Release Inventory (TRI). These chemicals tend to fall into a few main classes: metals or inorganics, aromatic hydrocarbons, or chlorinated hydrocarbons. Microbial-based treatment is only a viable option for organic compounds and nutrients (N, P). Metals may change redox state during biological treatment, but are not destroyed and will be present in the effluent wastewater or associated with the sludge. Therefore, physical and chemical processes are generally used to treat metals in the wastewater. As such, further discussion will be limited to organic compounds. The top chemicals on the TRI list that are amendable to biological treatment, in terms of quantity of treated on- or off-site or released (including air, water, and solids), are summarized in Table 2. Many of the most prevalent TRI compounds are relatively nontoxic. However, the uncontrolled release of these substances into sanitary sewers or the environment can disrupt treatment or ecology. Therefore, pretreatment or permits regulate the quantities of specific chemicals allowable in the waste discharged from an industrial facility, in addition to the more commonly regulated bulk parameters (eg, COD, TSS, and total N). Many industries have modified their processes to use more environmentally compatible (less toxic and more degradable) compounds. In addition to the regulation of the concentration of specific compounds in industrial wastewater effluents, the aggregate toxicity of the wastewater may be regulated. This whole effluent toxicity (WET) is generally tested by short-term and chronic tests on aquatic life such as water fleas, shrimp, and fish.

Regardless of the specific compounds and sources, biological treatment processes typically offer the lowest cost alternative for degrading organic compounds in the wastewater. Biological processes can also be used to remove nitrogen and phosphorus. Nitrogen can be removed from the water via the following processes: organic-N is mineralized by aerobic heterotrophs to ammonia; ammonia-N is aerobically biotransformed to nitrate-N; and under anaerobic conditions, heterotrophic bacteria degrade nitrate-N to N₂, which equilibrates out of the water into the atmosphere. Phosphorus can be removed from the wastewater via accumulation in particular types of bacteria. The processes used to biologically treat industrial wastewaters are often similar to those that are widely used for municipal wastewater. However, the composition range of industrial wastewaters often requires a somewhat more engineered approach to the wastewater treatment. Many industrial wastewater treatment facilities also include pre- and post-treatment by various physical and chemical methods.

In addition to the biodegradation of waste components, a variety of microorganisms may be present in the wastewater itself. Pathogenic species are of concern due to regulatory limits. The removal of pathogens during wastewater treatment is usually tracked using “indicator organisms” such as total coliform or fecal coliform bacteria, which are generally associated with the gut of mammals. Other microorganisms in the wastewater are of interest because they can contribute to or compete against the waste-degrading bacteria. For example, winery and dairy wastewater typically contain significant quantities of yeast and bacteria, which

have been found as significant populations in the biological treatment units. In addition, there is an emerging concern that microorganisms in the wastewater may carry antibiotic-resistant genes. In particular, antibiotic-resistant bacteria have been found associated with animal wastes, and as such could be present in water used to washout dairy stalls, and so on. Although the animals are fed different antibiotics than are used for humans, the genes associated with resistance to animal antibiotics may also impart resistance to the antibiotics used for humans.

The use of molecular methods to characterize bacterial populations has been gaining popularity, although these methods have not been widely applied to characterize biological treatment processes for industrial wastewaters. These approaches provide tools to better understand the microbiology of a treatment system, particularly under upset conditions. Examples of molecular methods include those targeting bacterial cell membrane components and genetic material. Fatty acid methyl ester (FAME) is a method that extracts and quantifies the fatty acid components of cellular membranes, generating a profile or “fingerprint” of the microbial community. Denaturing gradient gel electrophoresis (DGGE) creates a community fingerprint based on the stage at which DNA melts in the presence of a denaturing agent into fragments; the fragments migrate through an electrophoresis gel to different extents creating different banding patterns. By comparing band location and intensity, variability in the structure of a microbial community can be determined. Further information can be gathered by removing the DNA from specific bands of interest and sequencing it to identify specific bacteria. These methods have been used to characterize microbial diversity in full-scale industrial wastewater treatment plants, and varying levels of species richness and diversity have been found to be associated with different processes.

Genetic methods can target microbial DNA or RNA with probes to identify specific species or groups of bacteria. The so-called full-cycle 16S rRNA approach has the potential to identify previously uncharacterized microbial populations in samples from natural and engineered environments. First, genomic DNA is extracted from all members of the microbial community, followed by 16S rDNA gene amplification by the polymerase chain reaction (PCR), cloning, and finally sequencing of 16S rDNA gene fragments. These sequences are then compared with a database to identify the bacteria and/or their closest relatives. This method is therefore able to determine the diversity of the members of the microbial community in a treatment system. Using the sequence information available from the clone library, 16S rRNA-targeted oligonucleotide hybridization probes can be developed. These probes can be used for fluorescence in situ hybridization (FISH). Examples of studies that have used molecular methods to characterize the microbiology at full-scale industrial wastewater treatment facilities are provided in Table 3.

Aerobic

In general, aerobic biodegradation processes for organic compounds are faster than anaerobic. Aerobic treatment processes require the supply of oxygen, and result in oxidation of organics to carbon dioxide and biomass. The biomass or “sludge” is a secondary by-product that may require further treatment. The oxygen supply can be expensive; it is usually supplied by blowers and aeration equipment, involving an energy input. More recently, oxygenation via membranes and co-reactors with algae have also been explored. This article covers typical aerobic treatment reactors used for industrial wastewater treatment, and highlights some specific examples of wastewater treatment by each of the most common reactor types: activated sludge (AS), sequencing batch reactor (SBR), rotating biological contactor (RBC), moving-bed biofilm reactor (MBBR), and submerged membrane bioreactors (MBR). In order for processes using suspended bacterial growth (AS, SBR) to work optimally, the biomass must be “settleable” in the form of flocs so that high biomass concentrations (and long solids retention times) can be maintained in the system. Alternatively, a membrane can be used to retain biomass in the system. Biomass can also grow attached to an inert media, such as in an RBC or biotrickling filter. The wastewater to be treated flows over the biofilms on the media, and leaves the reactor. These reactors therefore have the ability to retain slow growing bacteria. However, too much biomass will eventually clog the media. Newer treatment systems are hybrids of attached and suspended growth, such as MBBR.

Activated Sludge

Activated sludge processes are among the most common biological methods used to treat domestic wastewater in the United States. The process is also frequently used to treat various types of industrial wastewaters. Conventional AS has an aeration basin where oxygen is supplied and the contents of the reactor are mixed by this aeration process, followed by clarifiers where biomass solids are removed by gravity settling. The settled biomass is generally returned to the beginning of the aeration basin as “return activated sludge.” This results in an average biomass retention time (so-called solids residence time (SRT)), which is significantly longer than the hydraulic residence time (HRT). Because the treatment performance is dictated by maintaining high biomass concentrations in the aeration basin due to biomass recycle, it is important that the biomass forms aggregates termed “floc” that have good settling properties. When the biomass does not settle well, reactor upsets occur and treatment performance usually decreases. Molecular methods are being used to determine which bacteria might be linked with poor biomass settling.

Another important operational consideration is the amount of sludge wasted from the system; this stream of concentrated biosolids is a waste product that requires further treatment (such as per the Part 503 Biosolids regulations in the United States). Frequently, these solids are treated and used as soil amendments. However, the sorption of toxic compounds, particularly metals, to the biomass can limit the safe uses of these biosolids.

The aerobic bacteria in AS systems biodegrade organic compounds, with a high degree of mineralization to carbon dioxide expected. The amount of oxygen that must be supplied increases with increased organic loading. When the total concentration of carbonaceous chemicals in the wastewater is measured as BOD or COD, the approximate amount of oxygen that must be supplied to the system is known. Oxygen supply involves the bulk of the operational costs in these systems.

Nitrogen and phosphorus must be present at sufficient quantities in wastewater relative to organic loading to allow heterotrophic bacteria to assimilate the carbon and grow in an uninhibited manner. Many industrial wastewaters are deficient in N and P relative to carbon, requiring the addition of supplemental nutrients to meet cellular demand. Examples of nutrient-deficient industrial wastewaters can be found in Table 1; nitrogen will generally be deficient if the COD/TKN ratio is greater than 35:1, and phosphorus limiting when COD/P ratio is greater than 300:1. Thus, the brewery, food pickling, textile, and winery wastewaters are commonly N limited, while the metal working fluids, food pickling wastewater, and winery wastewaters are often P limited.

A suitable aeration system is a key design parameter for AS treatment. Most AS processes are aerated via fine bubble aeration. However, for very deep reactors (>20 m water depth), medium or coarse bubble aeration will be more energy efficient. For very high-strength organic wastewaters, aeration with pure oxygen rather than air may be advantageous. Jet loop systems are another method for supplying oxygen and mixing. Jet loop reactors (JLRs) are vertical systems that claim to achieve higher oxygen transfer at lower energy than conventional aeration. Jet loop reactors have been studied at a pilot scale for treatment of winery wastewater, olive oil wastewater, and brewery wastewater. The systems have high velocity of liquid exiting the venturi nozzle, which could exert selective pressure on the microbiology of the system via a combination of physical shear stress and temperature effects. Specifically, filamentous fungi and bacteria have not been reported in JLRs. However, these systems do not appear widely applied in full-scale industrial wastewater treatment.

In addition to removing carbon compounds efficiently via biodegradation, AS processes have also been used to remove nutrients including nitrogen and phosphorus via sequential processes. Aerobic autotrophic bacteria can nitrify ammonia to nitrite (so-called ammonia-oxidizing bacteria (AOB); typically β -Proteobacteria) to nitrate (so-called nitrite-oxidizing bacteria (NOB); such as *Nitrospira* spp.). Then under anoxic conditions, heterotrophic bacteria can denitrify nitrate to nitrogen gas (N_2). Sequential anoxic – aerobic processes with a “single sludge” circulated/recirculated through the reactors in series are generally used for N-removal from wastewaters, combining the benefits of denitrification in the presence of sufficient organic carbon with nitrification under lower carbon loading. Some biological phosphorus removal is also possible by starting the single sludge system with an anaerobic selector; the sequential anaerobic/aerobic processes encourage intracellular accumulation of P-deposits within the bacteria, such that biosolids waste from the system removes soluble P from the wastewater.

Due to the more complex microbiology that is needed to achieve these multiple goals in wastewater treatment (organic removal by aerobic heterotrophs, nitrification by aerobic autotrophs, and denitrification by anoxic heterotrophs), molecular methods have been used to characterize the microbial populations present in these treatment systems. These methods can be used to help determine the source of treatment problems such as incomplete nitrification due to toxicity or extended anaerobic periods that inhibit nitrifiers (see examples in Table 3).

Aerated Stabilization Basins

Aerated stabilization basins (ASB) are a potentially cost-effective alternative to AS treatment of industrial wastewater. ASB systems have typically lower capital, energy, and operation and maintenance costs than comparable AS systems. In particular, pulp and paper industries appear to be selecting ASBs for wastewater treatment over AS systems. Pulp and paper industry wastewater contains variable-quantity contributions from four to five major process areas with significantly different wastewater chemistries, a wide range of apparent molecular weights (AMW) for organic wastewater components, and a brown color due to high-AMW dissolved lignin. Because AS systems do not handle shock loads efficiently, the installation of flow equalization, neutralization, and sedimentation units prior to the AS unit is common. Mechanically aerated stabilization basins represent about half of the lagoon systems and have the best performance of the lagoon types. There are two classes of mechanically aerated stabilization basins: completely mixed and partially mixed. The large majority of ASBs in the pulp and paper industry are partially mixed. Mixers in the systems also achieve aeration. The mixers used include jet aerators, surface aerators, static aerators, and submerged fine bubble diffusers. In the ASB process, the HRT and SRT are the same at ~5 to 15 days. For pulp and paper wastewater treatment, supplemental nutrient addition is needed, but at lower rates than in AS systems. Properly operated ASB systems can reach the comparable effluent BOD and nutrient concentrations to AS systems. ASB systems are more forgiving in responding to influent quality and flow variations and are simpler to operate. Settled secondary solids in an ASB system reduce in volume through hydrolysis to typically 10% concentrations. At periods up to 20 years the accumulated solids must be dredged, dewatered, and disposed. ASBs, because of their longer hydraulic retention times, tend to have their effluent wastewater temperature approach ambient air conditions. This is desirable during summer conditions, but can be a treatment problem in cold climates. Loss of an insulating foam cover is a greater problem for ASB systems. ASB systems typically require supplemental cooling equipment to attenuate the high influent temperatures of the wastewater. A naturally aerated “polishing” pond sometimes follows ASBs.

Sequencing Batch Reactors

In SBRs the treatment and settling of biomass are done within a single tank, unlike AS reactors. This may result in a smaller footprint overall than the AS process. The technology is becoming more popular in Germany, with 51 SBR plants for industrial wastewater treatment in operation; however SBRs yet represent less than 1% of the German wastewater treatment plants. A review of 29 full-scale SBR plants treating industrial wastewater in Turkey was presented by Artan *et al.* (2003). SBRs are used for food processing, pharmaceutical, textile, and other wastewaters treating 12–4800 m³ day⁻¹ of flow, inlet COD 600–12,000 mg L⁻¹, cycle times of 6–168 h, HRT 12–200 h, and recycle ratios (carry-over volume to new feed volume) of 0.2–4.8. These plants achieved effluent COD of 50–2000 mg L⁻¹, representing 77–98.5% removal. The advantage of the SBR systems was largely for high strength and variable quality wastewaters. SBRs are generally more automated in their operation than AS systems. SBR effluents generally contain less SS than AS systems. SBRs are somewhat less common at large wastewater plants due to the fairly high area required for the multiple reactors needed to treat continuous inflow. The operation of the SBR can be varied within a treatment cycle to enable different metabolic processes (such as anaerobic or aerobic) to predominate. This makes it particularly suited to simultaneous carbon and nitrogen removal.

Tannery wastewater is an example of a strong wastewater with high carbon and TKN. High chloride, sulfide, and chromium in the wastewater are potentially inhibitory to heterotrophic and nitrifying bacteria. Lab and pilot-scale studies have found comparable SBR performance to the full-scale AS systems on-site. These systems were operated with supplemental P addition, cycle times of 8–24 h, HRT 0.8–3 days, and SRT 15–17 days. Full-scale SBR systems have been used to treat brewery, winery, and pulp mill wastewaters and tanker truck wash water. These systems had 12–24-h cycles and achieved >93% COD removal.

Specific industrial chemicals have been shown to upset biological treatment in SBR systems. This is a disadvantage compared to complete mixed AS systems, which quickly dilute toxic concentrations of inlet spikes, versus the batch treatment where inlet concentrations are only attenuated by the carry-over biomass from the previous treatment cycle. Nitrification and low-temperature conditions seem particularly sensitive to these problems.

Rotating Biological Contactor

RBC treatment uses partially submerged rotating disks on which biomass can grow. As the disks rotate, the attached bacteria are sequentially exposed to the air, where they acquire oxygen and wastewater. Additional bacteria are also suspended in the wastewater treatment reactor. Energy is consumed by the large motor required to turn the biodisks, which can range in size from 3.5–5 m in

diameter. Rotational speeds are slow, at about 1 rpm. RBCs are fairly uncommon in industrial wastewater treatment, and have also largely fallen out of use in municipal wastewater treatment. A search of peer-reviewed literature found only five citations to full-scale RBC and industrial wastewater treatment. All except one citation were RBCs treating combined dairy wastewater with municipal wastewater, and all citations were before 1997. Supplemental aeration in the first and second stages that were often overloaded significantly improved the RBC treatment performance and were more robust against changing organic loading rates due to variable inlet wastewater quality. Winery wastewater during grape harvest has been treated in pilot-scale RBC reactors. Yeast species that are naturally associated with grapes (*Saccharomyces cerevisiae*, *Candida intermedia*, and so on) were found to be co-dominant in the attached biofilms with bacteria, indicating the potential importance of inlet microorganisms on the treatment.

Hybrid Suspended and Attached Growth Systems

Hybrid systems combine some characteristics of both suspended growth and attached growth biotreatment systems. There are three main types of hybrid treatment systems used for industrial wastewater treatment: the MBBR, integrated fixed film activated sludge (IFFAS), and biological aerated filters (BAFs). In each case, a few key companies have patented versions of the technology and market specific varieties. In general, all of the hybrid systems contained a solid media inside the traditional AS basin. This media is retained in the reactor and provides a support matrix on which attached biofilms form. Therefore, higher organic loadings can be treated in the same overall reactor volume due to the higher overall biomass in the reactor. This allows a smaller footprint for the wastewater treatment facility. In addition, the process is less reliant on the performance of the secondary clarifier and upsets in biomass sludge settling, because the attached biomass is retained regardless. In addition, specialized subpopulations of microorganisms can be retained in the fixed films rather than washed out of the reactor, and therefore better able to respond to intermittent loading of various compounds.

Moving-Bed Biofilm Reactor

Since the early 1990s, MBBRs have been in development and use, beginning in Norway and Europe and more recently expanding to applications in the United States. There are more than 400 large full-scale operations in 22 different countries. For industrial wastewater treatment, MBBR systems have been used to treat food industry, dairy, chemical plant (high in aniline, cyanides, and diphenylguanidine), flavor production, slaughterhouse, refinery, and pulp and paper wastewaters. Buoyant plastic media is aerated and suspended in a tank. Polyethylene Kaldnes media (2–50 mm long $\times$ 9–64 mm diameter) is one example, and has been the most widely reported for use at full-scale industrial treatment facilities. At typical carrier loading, this results in a specific area of biofilm growth of about $350 \text{ m}^2 \text{ m}^{-3}$ reactor volume. A sieve at the reactor outlet (with approximately 5–7 mm openings) is used to retain the media in the reactor. Alternatively, the LINPOR system uses foam cubes ($\sim 1.5 \text{ cm}$) as packing media. Circulation in the tanks by aeration or submerged mixers maintains movement of the media, and this agitation dislodges excess biomass from the carrier media and prevents clogging. Waste sludge sloughed from the media is collected in secondary clarifiers, similar to a trickling filter. This sludge is not recirculated. Oxidic zones can remove BOD and ammonia, and anoxic zones can remove nitrate. Phosphorus removal will not occur in the bioreactor.

One advantage of these systems is that the media can be added into existing AS basins to increase the biomass in the system. Municipal wastewater treatment systems have increased the total biomass in retrofitted AS basins by as much as a factor of 2. Most of the biomass in an MBBR (>90%) is attached to the media rather than suspended in the liquid. The MBBR system is also less prone to process upsets from poorly settling biomass than AS systems, since much of the total biomass in the system is attached on the retained media rather than being returned to the reactor as underflow from a secondary clarifier. LINPOR reports full-scale use of their technology for primarily municipal wastewaters, with one paper industry installation ($9000 \text{ m}^3 \text{ day}^{-1}$, inlet COD=400 mg L^{-1} , and effluent <70 mg L^{-1}) and a coke oven installation ($1,25,000 \text{ m}^3 \text{ day}^{-1}$, COD=280 mg L^{-1} and N=50 mg L^{-1}).

In some cases, MBBRs have been used as roughing filters ahead of downstream treatment processes, including conventional AS. In this configuration, significantly higher loadings can be applied since high removal efficiency of carbon and/or nitrogen is not required. For example, surface area loading rates (SALR) of 20–53 $\text{g COD m}^{-2} \text{ day}^{-1}$ and 10–25 $\text{g BOD m}^{-2} \text{ day}^{-1}$ have been reported ($\sim 2\text{--}5 \text{ kg COD m}^{-3} \text{ day}^{-1}$). Given the observed removal efficiency, this translates to removal rates of 17–42 $\text{g COD m}^{-2} \text{ day}^{-1}$ and 8–18 $\text{g BOD m}^{-2} \text{ day}^{-1}$. These values are expected to vary widely based on the amount of soluble biodegradable organic matter in the total COD. Nitrogen removal up to 0.83 $\text{g NH}_3\text{-N m}^{-2} \text{ day}^{-1}$ has been reported.

Another variation on MBBR technology is to add the plastic media into a sequencing batch reactor. This so-called sequencing batch biofilm reactor (SBBR) combines the advantages of an SBR with the biomass retention properties of attached biofilms. Most of the published studies on SBBRs are from laboratory-scale experiments with various synthetic wastewaters. A few pilot-scale studies have been reported with industrial wastewater, with reported removal rates of 0.3–9.1 $\text{kg COD m}^{-3} \text{ day}^{-1}$.

Integrated Fixed Film Activated Sludge

IFFAS is a hybrid process in which buoyant media is aerated and suspended along with mixed liquor in AS basins. A variety of medium types can be used. Rope-like Ringlace was developed in Japan in the 1970s and has been used in more than 400 locations

worldwide. Biofilms develop on the medium, increasing the overall biomass concentration in the AS basins. Frequently, this medium is added to existing AS basins to retrofit the plant to treat greater flow rates and/or achieve better removal of BOD and nitrification. Incorporation of the medium into an AS basin in sequence with traditional anaerobic and anoxic stages can achieve denitrification and biological phosphorus removal. Minimal peer-reviewed studies on IFFAS have been published. Most of the applications appear to be associated with municipal wastewater treatment.

Biological Aerated Filters

In a BAF, aerated wastewater flows through medium which acts as a filter. Most large systems are for municipal wastewater treatment, although there are at least 18 full-scale systems treating pulp and paper mill effluent and a number of smaller plants in Japan treating various industrial wastewaters. These systems have also been used for pretreatment of industrial wastewaters from food production, carpet dying, and pharmaceuticals to reduce high organic loads, with reported surface loadings of 15–30 g COD $\text{m}^{-2} \text{day}^{-1}$ and volumetric loadings of $\sim 4.5 \text{ kg COD m}^{-3} \text{day}^{-1}$. Higher organic loadings can be applied compared to conventional AS systems. These systems have also been reported to be more robust to changes in influent wastewater characteristics. No secondary clarifier is required. Phosphorus removal cannot be directly incorporated into the bioreactor. Two companies market the majority of the BAF processes.

Kruger/John Meunier, Inc.'s Biostyr uses plastic beads called BioStyrene (3.6 mm diameter; specific biofilm surface area $\sim 276 \text{ m}^2 \text{m}^{-3}$). Reported typical nitrification and denitrification rates in municipal wastewater treatment are about 0.9–1.2 kg N $\text{m}^{-3} \text{day}^{-1}$, achieving $< 5\text{--}20 \text{ mg L}^{-1}$ effluent N. Tertiary denitrification rates are higher at 3 kg N $\text{m}^{-3} \text{media day}^{-1}$ achieving $< 2 \text{ mg L}^{-1}$ effluent N. In highly loaded facilities with $\sim 0.5 \text{ day SRT}$, effluent BOD is $< 20 \text{ mg L}^{-1}$. Gravity backwashing about once a day is important due to headloss accumulation. This type of system has been used to treat dairy wastewater at a loading rate of up to 12 kg COD $\text{m}^{-3} \text{day}^{-1}$. The Biostyr system was also used to retrofit an AS plant to achieve nitrification at water temperatures as low as 7°C . The wastewater is first treated in AS basins, such that the BAF unit received $\sim 44 \text{ mg L}^{-1}$ BOD, 58 mg L^{-1} SS, and $32 \text{ mg L}^{-1} \text{NH}_4\text{-N}$ loadings.

Infilco's BIOFOR BAF uses expanded clay media with a mean diameter of 2.7 mm. In lab- and pilot-scale tests it has been determined that the typical packed-bed macroporosity is ~ 0.4 , with 1333 m^2 of carrier interfacial surface area per m^3 of reactor volume. The media bed depth is typically 3 m. In municipal wastewater treatment applications, the system can achieve effluent inorganic N less than 2 mg L^{-1} and 4–5 mg L^{-1} total N. Backwashing normally occurs once every 24–48 h and can be controlled based on elapsed time and/or accumulated headloss across the filter bed. BIOFOR systems are in operation at over 100 locations worldwide, treating from 380 to 416,000 $\text{m}^3 \text{day}^{-1}$ each. This type of media was used in a pilot study to treat citrus industry wastewater with inlet COD = 2400–5800 mg L^{-1} , BOD₅ = 1580–3900 mg L^{-1} , and pH 6–7.2. To reliably meet the effluent standard of 1100 mg L^{-1} effluent COD, volumetric load less than 72 kg COD $\text{m}^{-3} \text{day}^{-1}$ and hydraulic load less than 0.98 m h^{-1} was recommended. To achieve less than 600 mg L^{-1} effluent COD, a maximum load of 20 kg COD $\text{m}^{-3} \text{day}^{-1}$ and hydraulic load of 0.36 m h^{-1} was recommended. Cocurrent flow was more effective than countercurrent flow.

Another alternative media used is 2–3 mm diameter sand. This process has been used at a full-scale treatment facility treating up to 654 $\text{m}^3 \text{day}^{-1}$ of ammonia liquor from a coke plant. The six aerobic upflow filters are each 2.9 m wide, 6.5 m long, and 5.5 m high, with a total of 42.5 $\text{m}^3 \text{min}^{-1}$ of air added. Removal efficiencies are greater than 99, 78, and 99.9% for thiocyanate, ammonium, and phenols, respectively.

Membrane Bioreactors

MBRs are rapidly gaining popularity for industrial wastewater treatment. In North America, the first full-scale industrial treatment MBRs was implemented in 1991. In Europe, more than 100 full-scale MBR plants for industrial wastewater treatment are in operation, compared with only 39 systems reported in North America. Membrane bioreactors have the advantage of retaining biomass in the treatment reactor via the filtration of the effluent wastewater through the membrane. Most commonly the membranes are in the ultrafiltration (UF) range, with pore sizes 0.1–0.4 μm . In some cases, microfiltration (MF) membranes are used. Originally, the systems were operated with external membranes following the AS basin, replacing conventional secondary clarifiers. Biomass was returned to the reactor using a recirculation loop. In the newer configuration, the membranes are submerged directly in the bioreactor. The biomass is therefore a combination of suspended in the liquid and attached to the surfaces of the membranes. The systems therefore combine the aeration basin and clarifier common to AS systems in a single basin. Very high biomass concentrations can be retained in the system, with 12–15 g L^{-1} typical and as high as 30 g L^{-1} , without worrying about upsets from poorly settling flocs. Very long SRT is usually maintained in the system, and overall sludge wasting is generally less. In North America, GE is a popular manufacturer of submerged hollow-fiber membranes for industrial applications.

The primary disadvantage of the MBR system is the higher overall operating cost due to energy consumption, largely for pulling water through the membranes and the frequent cleaning cycles to minimize membrane fouling. Cornel and Krause (2006) noted that 0.4–4 kW h m^{-3} treated wastewater is typically needed for pump energy. For aerobic treatment systems, oxygen supply is also required. This can be provided via conventional bubble aeration or using submerged membranes for aeration. The energy needed for oxygen supply is typically on the order of 0.3 kW h m^{-3} for municipal wastewater; with higher amounts needed for wastes with greater COD.

A key concern with MBRs is avoiding membrane fouling. Fouling reduces the flux through the membranes and increases the energy consumption. To avoid problems, the influents wastewater is generally screened first, often through a sieve of ~ 0.5 mm. Common approaches to minimize fouling with submerged hollow fiber membranes include: in situ backwash with permeate every few minutes on an automatic schedule; chemically enhanced backwash on an automatic schedule approximately every day; maintenance cleaning with acids on a weekly basis, and infrequent (1–2x/year) ex situ intensive cleaning.

Most of the industrial wastewater treatment applications for MBRs in Europe are used for pharmaceutical, chemical, and food industry wastewaters, treating $50\text{--}1840\text{ m}^3\text{ day}^{-1}$. In North America, MBRs are used primarily for food and beverage processing and chemical plant wastewater, treating $19\text{--}18,925\text{ m}^3\text{ day}^{-1}$. Case studies reported include a pharmaceutical/chemical industry wastewater treatment facility with three AS tanks followed by four zenon hollow fiber immersed external membrane units with $15,840\text{ m}^2$ membrane surface. Inlet average COD and ammonia-N were 3500 and 100 mg L^{-1} , respectively; effluent contained 300 and $<1\text{ mg L}^{-1}$, respectively. The averaged flux was $12.5\text{ L m}^{-2}\text{ h}^{-1}$ and MLSS was $12,000\text{ mg L}^{-1}$. Another example is the full-scale MBR plant treating pharmaceutical wastewater in California. The operating liquid volume is approximately 147,000 gallons and the system is designed to treat 5 gallons per minute of wastewater at a feed total organic carbon (TOC) concentration of $14,000\text{ mg L}^{-1}$. The system contains four Model 500C Zeeweed modules (pore size, $0.03\text{--}0.04\text{ }\mu\text{m}$) with a total membrane area of 186 m^2 . The system is designed to operate at $10,000\text{ mg L}^{-1}$ biomass as TSS in the reactor. To avoid fouling that significantly increases the vacuum required to draw the liquid across the membranes, the system automatically backpulses permeate plus $3\text{--}5\text{ mg L}^{-1}$ sodium hypochlorite (bleach) for 60 s every 20 min. Once per day, a more vigorous cleaning procedure of maximum 20 min with $\sim 200\text{ mg L}^{-1}$ hypochlorite is conducted.

In a case study treating tannery wastewater, Reemtsma et al. (2002) found that the MBR with UF membranes did not improve the removal of poorly biodegradable polar organic compounds, such as naphthalene disulfonate, and benzothiazoles, compared to conventional AS treatment. Other laboratory studies have explored the suitability of MBR technology for chemical production, food production, paper mill, pharmaceutical, soap production, and various textile wastewaters with varying degrees of success.

Irreversible fouling of membrane surfaces is a significant problem. It is hypothesized that different microbial communities may be associated with irreversible clogging, and that different operating conditions can be used to select for microorganisms less associated with irreversible clogging. This is an active area of research.

Novel types of MBRs are also being explored for industrial wastewater treatment. A recent review article by Yeo et al. (2015) described high-retention MBRs and extractive MBRs. The high-retention MBRs are designed to retain target pollutants, and therefore have pore sizes that are smaller than typical, including nanofiltration MBRs, forward-osmosis MBRs, and membrane distillation bioreactors. Extractive MBRs are used to separate the biodegradable organics that are being targeted for treatment from aqueous conditions that are unsuitable for direct biotreatment, such as extreme pH or high salt concentrations. Unique materials are being tested for these membranes. To date these systems have only been explored in laboratory and pilot scale tests. Further developments are needed before these systems will be viable for full-scale treatment.

Anaerobic

Anaerobic processes degrade organics in the absence of oxygen. A significant advantage is that the high energy required for aeration of aerobic treatment systems is not needed; a potential savings of $\sim 1\text{ kW h kg}^{-1}$ COD removed. Another notable feature is the potential production of methane, which can be captured and used as an energy source, at a theoretical maximum energy yield of 3.8 kW h kg^{-1} COD removed. The biomass yield during organic degradation is also lower than aerobic processes, resulting inasmuch as 90% less by-product sludge. These systems can be used to encourage water reuse in factories. These factors indicate that anaerobic treatment may have significant advantages over aerobic processes and overall may be more sustainable for the environment.

Anaerobic treatment may be better suited to some waste types given the organic and nutrient concentrations present. The C/N/P ratio in typical winery wastewater is unbalanced for aerobic treatment and requires N and P addition; however, the 800:5:1 C/N/P ratio (BOD₅/N/P 333:3.3:1) is suitable for anaerobic treatment. The seasonal nature of the wastewater production at small wineries poses an additional challenge for anaerobic systems because they generally have longer start-up times due to lower cell yield. It has also been reported that the presence of a high concentration of sodium (such as $4600\text{--}14,000\text{ mg L}^{-1}$ and $200\text{--}250\text{ mmol L}^{-1}$) is inhibitory for anaerobic biological treatment.

VanLier conducted a review of anaerobic technologies and implemented full-scale industrial wastewater treatment. From 1998 to 2004, of 519 systems, the most popular were upflow anaerobic sludge blanket (UASB), internal circulation (IC), expanded granular sludge bed (EGSB), lagoon, hybrid, completely stirred tank reactor (CSTR), and anaerobic filters (AF) or fluidized-bed (FB) technologies at 36, 34, 17, 4, 2, 2, 1, and 1%, respectively. Note that this represented a shift to more granular sludge based and super high rate based systems (FB+EBSG+IC=52%) compared to the 1383 anaerobic treatment technologies implemented from 1981–98 (super high rate=8%). High rate anaerobic treatment was commonly applied to food processing wastewater from industries such as sugar, potato, distilleries, wineries, fruit juice, starch, beer, and soft drinks. Anaerobic biotreatment applications in paper mills and chemical wastewater are also increasing. In another survey paper, Austermann-Haun et al. (1999) noted that of the 125 full-scale methane reactors treating industrial wastewater in Germany; 43 were sludge blanket reactors, 33 fixed-film reactors, 11 CSTRs, and the rest were various hybrid systems. Examples of anaerobic treatment of industrial wastewaters in various anaerobic reactors are provided in Table 4. Note that AF and FB systems are attached growth while the remainder are suspended growth, with hybrid systems containing a combination of attached and suspended biomass.

Upflow Anaerobic Sludge Blanket

The most widely applied form of anaerobic wastewater treatment is the UASB. In these systems, the biomass tends to form granular agglomerates that have very good settling properties. The systems tend to work best with high strength wastewaters and at higher temperatures. The conventional UASB process can accommodate a fairly high organic loading rate, in the range of 5–15 kg COD $\text{m}^{-3} \text{ day}^{-1}$ for readily biodegradable wastewaters. UASB systems have been used to treat wastewater from alcohol distilleries, fruit juice, meat packing, paper mills, potato processing, slaughterhouses, and sugar processing plants. Problems sometimes noted with UASB systems include difficulties when treating wastewater containing high TSS content, foaming when treating high amounts of fats, lipids, and proteins; clogging of the sludge bed when treating fatty effluents; and biomass washout.

UAB reactors can be operated under a variety of temperature regimes ranging from psychrophilic ($<20^{\circ}\text{C}$), to mesophilic (35°C), to thermophilic (55°C). Mesophilic is the most common. External heating is generally needed to operate at mesophilic or thermophilic temperatures; this may be supplied by using the methane gas produced in the digestion. The high temperature of effluent water from the pulp and paper industry ($50\text{--}60^{\circ}\text{C}$) may be particularly suited to thermophilic anaerobic digestion, although at present only laboratory studies on these systems are known. Different bacterial species will generally survive at mesophilic versus thermophilic temperatures.

To improve the process performance of UASB reactors, modifications including EGSB and IC have been made. EGSB is designed for a faster upflow velocity of water through the sludge bed ($4\text{--}10 \text{ m h}^{-1}$) than traditional UASB reactors ($0.5\text{--}2 \text{ m h}^{-1}$). This increased flux partially fluidizes the granular sludge bed, resulting in improved contact between the wastewater and the sludge. The IC process has two UASB compartments on top of each other. In the first, bottom stage, most of the biogas is produced. This gas is trapped in an internal gas hood, rises through a riser pipe to a gas liquid separator, and then liquid flows down a downcomer pipe to the first stage. In this manner, the biomass production drives internal circulation of the wastewater. The second, top stage functions as biomass retention and polishing. The number of full-scale plants using these enhanced processes has been increasing year by year. In these EGSB and IC systems, higher organic loading rates ($15\text{--}45 \text{ kg m}^{-3} \text{ day}^{-1}$), tall reactors 12–20 m high, and high upflow velocities of $8\text{--}30 \text{ m h}^{-1}$ are common. At higher organic loading rates, the higher intensity of biogas production tends to cause sludge washout from the reactor. This problem can be addressed using a compartmentalized UASB reactor, which is equipped with multiple numbers of gas–solids separators (GSS).

Anaerobic Sequencing Batch Reactor

Anaerobic sequencing batch reactors were first developed in the early 1990s to treat landfill leachate and high strength organic wastewater. Like aerobic SBRs, there is a treatment cycle of four discrete steps: fill, react, settle, and withdrawal. These cycles should be as frequent as possible, without idle time. The reactors are amenable to automatic process control, enabling operational flexibility. These systems have been used to treat piggyery and slaughterhouse wastewater, winery wastewater, and landfill leachate.

Anaerobic MBR

Most of the literature citations of anaerobic MBRs are for domestic wastewater treatment. Cake formation is noted as a major cause of flux decline. This may result in irreversible clogging and flow membrane flux per headloss. One contributor to this problem may be that the selective pressure to maintain microbial granules is gone so that the biomass quickly degenerates into loose floc even if seeded with granular sludge material. Scaling due to high concentrations of carbonates may also be a problem. Lab-scale studies treating starch wastewater found that a membrane significantly improved the performance of the acid fermentation reactor but had little impact on the efficiency of the methane fermentation tank; other lab-scale studies have been conducted with brewery, fermentation, food, and pulp and paper wastewaters.

Coupled Anaerobic/Aerobic Treatment Processes

By combining anaerobic and aerobic treatment processes, the overall treatment of industrial wastewater may consume less energy, more fully mineralize complex organic contaminants, and enable optimum nutrient removal. Typically, the anaerobic stage is first. This achieves organics removal without requiring energy to supply oxygen and at lower sludge yield. Useful by-products such as methane gas can be generated. The step can generally remove 80–90% of the organics. The second aerobic stage can polish the wastewater to meet stringent discharge limits for organics, and may also remove nitrogen and phosphorus. The specific reactor types selected for the anaerobic and aerobic stages can vary. Some examples are provided in Table 5; Chan et al. (2009) provide about 20 additional examples in their review paper. The UASB-cyclic AS systems for brewery wastewater treatment have been reported to reduce sludge production by a factor of 5 and lower energy consumption by a factor of 3 compared to existing two-stage aerobic treatment systems, with 11 full-scale systems reported.

At full-scale plants in Germany treating wastewater from beet sugar factories, potato processing, breweries, and potato and wheat starch factories, the wastewater is anaerobically pretreated and then followed by an aerobic stage with nitrification and denitrification. In these cases, there is generally a by-pass of some fraction of the wastewater around the methane reactor to supply enough organic carbon for the denitrification stage. The authors recommend that 50–70% of the AS tank be used for denitrification.

Table 5 Examples of sequential anaerobic:aerobic treatment of industrial wastewater

Wastewater source	Scale; <i>Q</i> and OLR	Anaerobic stage	Aerobic stage	References
Brewery	Full; 24–417 m ³ h ⁻¹ 2200–32,280 kg COD day ⁻¹	UASB ~7 h HRT 9 kg COD m ⁻³ day ⁻¹	Cyclic AS ~20 h HRT 0.4 kg BOD m ⁻³ day ⁻¹	Gerards et al. (2005)

Some recalcitrant organic compounds can only be mineralized by anaerobic and aerobic biodegradation processes in series. For example, azo dye decolorization can occur via anaerobic reduction or cleavage of the azo bond followed by mineralization of aromatics and amines under aerobic conditions. Therefore, these sequential systems have been studied for treatment of dye water, such as sequential UASB/AS systems.

Natural Treatment: Wetlands

In addition to engineered treatment of industrial wastewaters in tanks and constructed basins, there are various examples of industrial treatment in lagoons and constructed wetlands. These processes are most often used in agricultural areas where large areas of land are available, rather than urban industrial settings. There are two predominant types of constructed wetlands: free water surface (FWS) and subsurface flow (SSF) wetlands. In the FWS wetland, also called surface flow wetlands, there is freestanding water over the soil bedding of the wetland. In contrast, the SSF wetland has a greater depth of granular media into which the plants root, and no water flows above the surface of the media. Typical depths of granular media are 1–1.5 m in SSF wetlands, although the actual water depth flowing through the bed may be much less (as low as 0.15 m reported). In both types of wetlands, good engineering design dictates that the wetland is constructed on a low permeability liner. The liner can be natural material (such as clay) or more commonly a geomembrane material such as high-density polyethylene. The liner prevents wastewater that has yet to be fully treated from leaching out of the bottom of the wetland and contaminating the underlying groundwater.

Both systems achieve removal of organics and nutrients by a combination of plants and associated microorganisms. The types of plants in the wetland are critical to the type of treatment efficiency achieved. The plants evapotranspire water, uptake nitrogen and phosphorus, and can impact the redox conditions. Common plants in constructed treatment wetlands include bulrush (*Typha*), grasses, and reeds. Excess plant growth over time may require harvesting. This has been shown to be true in water hyacinth ponds.

The redox conditions in a wetland range from aerobic to anaerobic. Oxygen is available near the free water surface due to dissolution from the bulk atmosphere and near plant roots that excrete oxygen. Anaerobic conditions occur at depth and in the lower soil layers. Pathogens are also attenuated through the treatment process via filtration and natural die-off under environmental conditions and bacterial competition. Removal of fecal coliforms (FC) typically range from one to three orders of magnitude.

Unless a large amount of land is available to allow long residence times, these wetland treatment processes are used for polishing and nutrient removal after the bulk of organics and solids have been removed. Typical natural processes used for wastewater treatment before wetlands include solids settling and various types of lagoons (anaerobic, facultative, and aerobic). Solids removal is particularly important in SSF wetlands, where high solids loading may otherwise clog the porous media. Therefore, presettling is a common pretreatment. Even still, the inlet zone of SSF wetlands often contains coarse gravel to minimize clogging problems. The final effluent from wetlands is often reused for irrigation, agricultural “washing,” or other uses. Newman et al. (2000) cite the presence of ten constructed wetlands for agricultural wastewater treatment in North America. Examples of wetland treatment systems are provided in Table 6. Note that residence times are normally determined by nonreactive tracer studies.

Poor treatment efficiency in colder winter months outside the plant growing season may be a problem. However, some treatment occurs even at air temperatures as low as –8°C, water temperatures as low as 1.6°C, and with ice on the top of the wetlands. It has been reported that more TSS, TP, TKN, ammonia, and nitrate/nitrite are removed during the plant growing season than during plant senescence. In fact, effluent ammonia-N may be higher than inlet wastewater during the winter due to plant senescence. Owing to nitrifying bacteria, it is expected that N removal will be more temperature sensitive than carbon removal. Settling and increased storage may account for much of the contaminant removal during winter months.

3-Methyl-pyridine	Lab	Pre ozone bubble column produced formate, acetate, NH ₃	SBBR	Carini et al. (2001)

Coupled Biological With Chemical or Physical Treatment

The coupling of biological treatment with chemical or chemical treatment may improve the overall treatment of the wastewater. One of the most common approaches is to couple chemical oxidation with biological treatment. The most commonly used oxidant is ozone, with a few examples of Fenton's reagent and hydrogen peroxide use. Examples are summarized in Table 7. Ozone added into water causes both direct oxidation of organics with ozone and indirect oxidation with the hydroxyl radicals that ozone forms. In Fenton's oxidation, iron serves as a catalyst for hydrogen peroxide solution to form hydroxyl radicals. These radicals can oxidize most organic substances. Future ideas under exploration are ways to use solar collectors to power photocatalysis by TiO₂ or photo-Fenton oxidation. These types of systems would be more environmentally sustainable than traditional oxidant technologies.

Biological treatment processes may also be combined with absorption on activated carbon, to remove recalcitrant organic compounds. The bulk liquid concentration of toxic wastewater components is decreased by adsorption so that inhibitory effects on the bacteria are minimized. Volatile organics may be kept available to the bacteria instead of being stripped. Over time, if the recalcitrant organics are intermittently loaded, biodegradation may regenerate the sorptive capacity of the activated carbon. Kolb and Wilderer (1997) explored this type of system in a lab-scale SBR system treating benzene and 2-chlorophenol or trichloroethene plus phenol wastewater. They found that it was more efficient to sequentially load the activated carbon and then biologically regenerate it, rather than trying to simultaneously sorb and biodegrade the compounds in a single step. Another potential combination is steam stripping followed by biological treatment. This process has been used to treat Kraft Mill wastewater.

Future Outlook: Electricity Production and Other Electrochemical Technologies

High organic-strength industrial wastewaters may be well-suited for various microbial electrochemical technologies (METs) and bioelectrochemical systems (BES). The most widely studied of these processes are microbial fuel cells (MFCs), which produce electricity directly from bioactivity. MFCs have been studied for nearly 20 years, with success achieved in lab-scale systems. However, full-scale MFC treatment systems for industrial wastewater are not known (Logan et al., 2015); the reason for the lack of full-scale adoption is speculated to be largely due to the costs associated with the electrode materials. Types of industrial

wastewaters that have been tested in lab-scale MFCs include cattle manure, liquid cheese production wastes, and wastewater from chemical industries, dyes, glass industries, leather tanning, metal works, textiles, and vegetable oil industries. A different form of MET is a microbial electrolysis cell (MEC), which can produce hydrogen gas. Alternative methods of biohydrogen production were reviewed by Bobescu et al. (2016). With further development and exploration of lower-cost materials, these systems promise electricity and/or net energy production from waste, but even an energy-neutral process whereby the energy production meets the treatment demands for mixing, oxygen supply, etc. would be beneficial over many existing industrial wastewater treatment processes.

Conclusion

Microbiological-based wastewater treatment processes can degrade many of the organic compounds in industrial wastewaters, mineralizing them to carbon dioxide and/or methane. Specific reactor configurations are better suited to some types of wastewaters, although in general all of the main types of industrial wastes have been treated under both aerobic and anaerobic conditions with various reactor configurations for each. Therefore, the optimum waste treatment reactor will depend on site-specific constraints including land availability, operator skill and time, energy, and sludge disposal, just to name a few. Although typical reactor sizing and bulk organic loading rates are available, due to the variability of wastewater characteristics and potential presence of specific target compounds that may or may not be recalcitrant or inhibitory to bacteria, bench scale or pilot scale testing are often conducted prior to sizing the full-scale treatment facility. In general, these smaller scale results seem to be predictive of full-scale performance. If problems arise during full-scale treatment, molecular methods to characterize the microbiology may provide a good tool along with traditional physical (suspended solids) and chemical analyses (pH, nutrients, and organics) to diagnose the source of the problem. Advancements in technology continue, with a goal of improving treatment efficiency at lower cost. In the future, industrial wastewaters may provide an important source of energy, if issues such as material costs for METs and BES can be solved. Owing to the vast breadth of information briefly overviewed in this article, readers are encouraged to read further on the specific technologies outlined in this article.

Dry wines Wines with residual sugars lower than 10 g/L. Wines lacking sweetness.

Enology The science of winemaking.

Must Grape juice or mashed grape before and during fermentation.

Vinification The technology of wine making.

Viticulture The science of growing of grapes.

Defining Statement

Wine is an alcoholic beverage made by the fermentation of grape juice or other sugar-containing substrates including honey, sugarcane, fruit juices, and other plant juices containing sugars, such as palm tree sap, floral extracts, and *Agave*, the century cactus plant. Wine is distinguished from beer, in which the fermentable sugars are derived principally from starches by means of amylases produced in cereal grains, particularly barley, by germination or malting.

The term “wine” probably should not be applied to beverages that involve the hydrolysis of starch in cereals through ptyalin in saliva, the hydrolysis of starch to sugars via fungal or bacterial amylases, or the hydrolysis of starch to sugars and then fermentation of the sugars to ethanol by microorganisms. Thus, South American chicha, made by chewing maize and subsequently fermenting it, should probably be called a maize beer. Rice wine, such as Japanese sake, made by overgrowing boiled rice with *Aspergillus oryzae* as a source of amylases and then fermenting it with yeast, should probably more correctly be termed rice beer; however, accepted usage may preclude this.

This article will restrict the term “wine” to products made by the fermentation of sugar-rich substrates in which starch hydrolysis is not required.

Antiquity of Wine Fermentation

Wine fermentation is one of the oldest and perhaps the oldest fermentation known to humans. Honey diluted with rainwater ferments spontaneously with yeasts in the environment. Fruit juices ferment spontaneously with yeasts on the fruit. Although the most ancient fermented beverage produced on purpose was most likely beer, wine from grapes is the oldest wine produced. Although some legends may indicate pulque as very old fermented beverage, the absence of evidences cannot sustain those claims.

Wine was truly a gift of God (or nature) to primitive humans. Fruit juices ferment spontaneously, yielding a product that preserves and, in fact, enhances the fruit’s nutritive value and retains its essential flavors. The conversion of the sugar to ethanol and ethanol’s striking effect on the psyche of the consumer naturally led to the conclusion that the “spirit” of the fruit had been extracted for the benefit of the consumer.

However, the microorganisms responsible of this transformation were present on earth much earlier than humans. Microorganisms have the primary task of recycling organic matter, including sugars; yeasts in the environment ferment the sugars to alcohol as fruits become overripe and fall to the ground. Alcohol is one of the products of recycling reactions. It, in turn, is further fermented to acetic acid or respired to CO₂ and H₂O in continuing recycling reactions.

From the beginnings of civilization, wines have been associated with culture, art, and religion because early humans considered wine a miraculous conversion. For many years, the people responsible for the production of wine were considered as priests or similar, as they were handling the “miracle” of transforming the sugary liquid into a new product with euphoric effects and allowed new social relations.

Alcoholic beverages have always been closely related to politics, and even today governments use alcoholic fermentations as a major method of raising taxes. In the Hammurabi code there are already references to wine and frauds linked to it; also in the Bible there are several references to wine consumption and Noah’s drunkenness as result of the celebration after planting a vineyard. In very

[☆]Change History: November 2016. Albert Mas updated the text throughout the article.

This article is an update of K.H. Steinkraus, Wine, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 138–143.

primitive times in South America, emperors could hold office only as long as they provided the people with a sufficient supply of chicha. From ancient times, wines have played a vital role in religious ceremonies, and they continue to do so today. For many centuries, wine and beer had been the safest way to drink water and, thus, being a relevant part of the regular food intake of civilization.

Alcoholic Fermentation

The biochemistry of the alcoholic fermentation is among the most thoroughly studied enzyme–substrate sequences ever investigated. Black, in the 18th century, reported that ethyl alcohol and carbon dioxide were the products of sugar fermentation. Lavoisier, in the same century, reported that 95.9 parts of sugar yielded 57.7% ethyl alcohol, 33.3% carbon dioxide, and 2.5% acetic acid. Gay-Lussac was the first to show that glucose fermentation yielded approximately equal weights of ethanol and carbon dioxide (45 parts glucose yielded 23 parts alcohol and 22 parts carbon dioxide). Pasteur found that 100 parts sucrose yielded 105.4 parts invert sugar, which was fermented to 51.1 parts ethyl alcohol, 49.4 parts carbon dioxide, 3.2 parts glycerol, and 1.7 parts succinic acid. In Neuberg's normal fermentation, 1 mol of glucose yields 2 mol of pyruvic acid, which, in turn, yield 2 mol of carbon dioxide and 2 mol of acetaldehyde, which, in turn, are reduced to 2 mol of ethanol. Detailed research has shown that there are actually 12 intermediate steps between glucose and ethyl alcohol (the Embden–Meyerhof scheme), which account for the production of 2 mol of carbon dioxide, 2 mol of ethanol, and smaller quantities of glycerol from 1 mol of glucose.

Buchner in the 19th century produced ethyl alcohol from sugar using cell-free juice, made by grinding yeast cells with sand under pressure and filtering to remove the whole cells. This demonstrated that it was enzymes that were required for fermentation and not the whole cells themselves.

Yeasts

The principal microorganisms in the alcoholic fermentation of wines are yeasts belonging to genus *Saccharomyces*, in particular *Saccharomyces cerevisiae*. The taxonomy of *Saccharomyces* genus has suffered many revisions and, thus, it is possible to find many different names and species in the literature of wine making. However, nowadays there is a main consensus that *S. cerevisiae* is the main responsible for wine fermentation. Although yeasts belonging to genus *Saccharomyces* are generally present in the grapes or other fruits and they are capable of fermenting the juice to wine, it is a considered a good practice among winemakers, to inoculate pure cultures of selected wine yeasts. The main goal is the control of the alcoholic fermentation, in terms of good fermentation performance as well as a good quality final product. These yeasts are selected basically for the absence of off-flavors, but also for flavor, production of little or no foam, ability to ferment at low temperatures, or flocculation–sedimentation behavior.

Other wild yeast can be present during alcoholic fermentation, especially abundant in grapes and grape juices. Generally regarded as spoilage microorganisms, several efforts are oriented to prevent their growth during early stages of fermentation. Thus, to ensure that the selected wine yeast predominates over those wild yeasts and other microorganisms that may be present, it is also common practice to add 20–50 mg sulfur dioxide/L to the juice, usually in the form of bisulfite, before inoculating the selected yeast, which is generally tolerant or acclimated to these concentrations of sulfite. However, these non-*Saccharomyces* yeasts are also considered to provide some positive attributes to wine, such as more complexity, higher aroma concentration or even reduction of alcohol. Thus, some selected non-*Saccharomyces* yeasts are also available to be inoculated sequentially with *S. cerevisiae*.

S. cerevisiae and other wine yeasts have the ability to grow and metabolize sugars, such as glucose, fructose, and sucrose, aerobically or anaerobically. Aerobic growth yields far more energy and the yeasts multiply vigorously, but little if any ethanol is produced. However, in presence of high concentration of sugar and even in presence of oxygen, *S. cerevisiae* ferments sugar due to a complex inhibitory process of respiration known as Crabtree effect. Anaerobically, yeasts dissimilate glucose according to the Embden–Meyerhof scheme. Theoretically, 1 mol (180 g) of glucose yields 2 mol (92 g) of ethanol and 2 mol (88 g) of carbon dioxide. Actually, yields are slightly less because of the production of yeast biomass, glycerol and other minor compounds; nevertheless, it is practical to consider that 2 g of sugar yields slightly less than 1 g of ethanol. Anaerobic dissimilation of 1 mol of glucose yields 56 Kcal of energy to the yeast, part of which is used in the fermentation itself and a portion in multiplication of the yeast.

Yeasts multiply by budding, and the percentage of yeast cells showing buds when examined microscopically in culture or in a fermenting wine is a measure of the vigor of the culture.

When calculated on an overall fermentation basis, an individual wine yeast cell produces about 30 million molecules of ethanol. In the earlier stages of fermentation, a yeast cell may produce 100 million ethanol molecules. As the ethanol content reaches 12% v/v, the rate of ethanol production may fall to 10 million molecules.

Malolactic Fermentation

Another group of microorganisms accompanying the yeast in wine fermentations is the lactic acid bacteria. Lactic acid bacteria–yeast interactions are rather common in food and beverage fermentations. Grape juice contains organic acids, mainly tartaric acid and

malic acid. If the acidity is too high for the best flavor, it may be desirable to reduce it. Winemakers can take advantage of the spontaneous process led by lactic acid bacteria to ferment the malic to lactic acid, which decreases the total acidity and raises the pH of the wine. It also modifies the aroma, body, and aftertaste. If the grape juice has low acidity, malolactic fermentation may be undesirable because it will decrease the acidity still further, making the wine taste flat. Selected lactic acid bacteria starters are currently available to ensure the malolactic fermentation and the positive aromas that could be associated.

Malolactic fermentation could occur during the alcoholic fermentation, although it is most likely after the alcoholic fermentation is finished and nutrients from yeast lees are released. Spontaneously can also occur during holding before the final clarification and fining because it increases the microbiological stability, decrease fermentable carbohydrates, and produces inhibitory bacteriocins in the wine. If malolactic fermentation occurs in the bottle, it may result in cloudy wine or carbonation of a still wine.

Noble Mold

Under high-humidity conditions, unripened grapes may become infected with *Botrytis cinerea*, the noble rot. If the humidity decreases, the grapes lose moisture and, in fact, become shriveled. Such grapes yield a juice with higher sugar content, the grape flavor may also be concentrated, and the mold may introduce a delicate flavor. Under ideal conditions, very fine flavors can be produced from grapes infected with the noble mold.

Microorganisms Causing Spoilage in Wines

All the microorganisms, even those that are necessary for wine production, can spoil wine. In fact, one of the main characteristics to select a microorganism as starter culture is the ability to ferment without producing any wine spoilage. Thus, yeasts and lactic acid bacteria, fundamental for wine production, together with acetic acid bacteria are the major organisms causing spoilage in wines.

The main spoilage that microorganisms produce on wines are related to the production of acetic acid, which often derives also in the production of acetaldehyde and ethyl acetate, the production of haze or films on the surface and also the production of several phenolic compounds that remind horse sweat or mouse-like odor. Although the main producers of acetic acid are normally the acetic acid bacteria as the name points out, there are not the only ones that can produce it. Several non-*Saccharomyces* yeasts and lactic acid bacteria are also able to produce it in considerable amounts. The species of acetic acid bacteria that produce acetic acid are mostly, but not exclusively, from the genus *Acetobacter*. The process is highly aerobic and, in fact, grows on the surface of the wine if oxygen is present and could lead to the production of vinegar. The acetic acid bacteria are not generally a problem during alcoholic fermentation because carbon dioxide is being rapidly produced, and it displaces oxygen from the must, keeping it anaerobic. However, at the end of fermentation, oxygen exposure may facilitate the activity of these acetic acid bacteria.

One of the worst wine spoilages is produced by *Brettanomyces*, which produces off-flavors if it develops during aging storage. *Brettanomyces* produces of 4-ethyl phenol and 4-ethyl guaiacol, volatile phenols that are defined with descriptors such "mousy," "band-aid," horse sweat or horse stable, etc. and are defined as "*Brett* character" and it is clearly a serious defect of wine.

Microbiology of Sherry Wines

Sherry wines have an oxidized flavor, color, or aroma and are highly acceptable among many wine consumers. The oxidized flavor arises by conversion of a portion of the ethanol to acetaldehyde and other complex reactions. This is normally considered a defect in many wines; however, in sherry wines is its essential characteristic and oxidation is specifically sought. In a true fermented sherry, barrels are half-filled the still wine and the surface of the wine is exposed to air. Specific *S. cerevisiae* yeast strains develop a film, named "velo," which is the origin of the biological oxidation of the wine. Later they follow an aging process that could be "static" (always in the same barrel), or dynamic (more traditional). The traditional dynamic system, with several levels of barrels where the ones at the bottom are named "soleras" and hold the oldest wine, while the ones in the upper levels are increasingly younger wines ("criaderas"). Every year a portion of one third of the barrel is withdrawn from soleras and replaced with the corresponding wine from criaderas. Sherry wines can be aged for many years following this system.

Wine Grapes

Grape wines are made mainly from species *Vitis vinifera*. This is particularly true in Europe, where the major producers are France, Italy, and Spain. The native grapes in the United States belong to the species *Vitis labrusca* and several other species that have a

characteristic fruity, floral (“foxy”) aroma, distinctly different from *vinifera* grapes. *Vitis rotundifolia* is an important species in the southeastern United States. However, most American wine is produced in California, based on the cultivation of *V. vinifera*. *V. vinifera* wines are the most appreciated and recognized by the consumers and thus, the most spread throughout the world. *V. vinifera* is sensitive to *Phylloxera*, insect imported from North America, that destroyed all the European vineyards in the late 19th century. Nowadays, with some exceptions, most of the *V. vinifera* is grafted on American cultivars which are resistant to *Phylloxera*.

Wine Classification

Wines are classified according to color (white, red, or rose/pink) and how much ethanol and sugar they contain. The color of the wine depends on two main variables: the color of the grapes (mostly their skins, where the pigments are highly concentrated) and the production system. Red wines are produced from pigmented varieties and produced by maceration of the fermenting must with the skins of the grapes. White wines can be produced from either red or white grapes but without maceration with the skins. Rosé wines are normally wines from red grapes that follow a “white” fermentation after a short maceration with the skins.

Most of the grape juices are fermented to dryness that is until all the sugar is transformed into ethanol. Other wines are partially fermented and according to the sugar content can be defined as semidry, semisweet, or sweet. These wines with sugar left are very unstable microbiologically, unless sulfites or alcohol are added. The wines with added alcohol are named “fortified” wines and several worldwide known wines use this practice (Porto, Sherry, Marsala, Madeira, some sweet muscat, “vins doux naturels”, etc.).

Finally, wines can be also denominated from the grape variety used. There are thousands of cultivars of *Vitis* species. Many yield wines with flavors and aromas reflecting their distinct type. The reader is referred to section “Further reading” for more information. A very wide variety of flavors, aromas, and colors of wines can be produced. The climate and the soil on which the grape variety grows and the particular growing year can have a marked effect on the flavor of the resulting wine. This leads to “vintage” years, in which a particular variety yields unusually high-quality wine. One of the most important wine classifications is the regional or geographical origin of the wines. This derives directly from the soil, climate and varieties that are used in a given area and determine a definite or typical character. This wine typicality is protected by an “Appellation of Origin” label or similar (the names are country specific and also their regulations). Normally all of them have a regulatory board that guarantees the origin of the product and, thus, its typicality.

Steps in Manufacture of Wine

1. Harvesting: grapes should be harvested when they are at their peak of maturity and desired flavor with a high sugar content and desirable acidity. They should be as intact as possible and be processed quickly.
2. Destemming: is the separation of the grapes from the stems. For white wines, the stems are removed and the grapes are crushed. The skins are retained for red wines. Sulfite may be added to inhibit the oxidation and growth of the natural microbiota.
3. Pressing: it is the separation of the juice from the skins, seeds, and pulp – the pomace. Pectinase may be added to facilitate juice extraction. Free-run juice, the juice running from the press before pressure is applied, is considered to be best for the highest quality wines.
4. Fermentation: fermentation can proceed either through the action of the naturally present yeast or by the inoculation of a selected pure yeast culture. In industry, the yeast inoculum may be produced in the company’s own laboratory (normally restricted to large companies) or it may be purchased as an active dry yeast from companies specializing in the production of industrial cultures. Fermentation temperature is generally 10–18°C for white wines and somewhat higher (20–28°C) for red wines. The higher the temperature, up to about 30°C, the more rapid the fermentation; however, the slower, lower temperature fermentations are considered to lead to higher-quality wines because less volatile aroma is lost. In red wines, temperature is a compromise between the color extraction from macerated skins and the loss of aromas. As the fermentation proceeds, the actively metabolizing yeasts produce heat and the temperature of the must tends to rise. If not controlled, the temperature can reach a level at which yeast cells are killed or the ethanol becomes so inhibitory that the maximum ethanol content is decreased. The sugar content of the juice must be sufficient to yield a wine with the desired alcohol content. This requires a sugar content of about 13% w/v to yield a 7% v/v alcohol wine or about 22% to yield a 13% v/v alcohol wine. The sugar content of the juice may be raised before or during fermentation to adjust the final ethanol content. Water may be added to lower the acidity where the law allows amelioration. The governing bodies of wine making (Appellations of origin, International Organization of Vine and Wine, national or local governments) normally regulate these practices of water or sugar addition and they are banned in many places where high-quality wines are produced.

A weight of carbon dioxide gas almost equivalent to the weight of ethanol produced is released during fermentation. This causes the fermentation to “boil” during its most active phases.

The fermentation gradually ends as the fermentable sugar is consumed. With red wines, the pomace, skins, seeds, and other insoluble matter must be removed. This is usually performed when the color and tannin extraction have reached the maximum toward the end of fermentation or several days after completion of the fermentation. The separation of the pomace is accomplished by draining and pressing. With white wines, the pomace has already been removed during the pressing before fermentation.

5. Racking: as the fermentation nears completion, the yeast cells tend to settle, and after fermentation has been completed, the wine can be decanted or siphoned (racked) as the first step in clarification of the wine. Racking is repeated periodically until most or all the yeast cells (the lees, tartrate crystals, and other insoluble particles) have been separated from the wine. This may be combined with cold stabilization, which is accomplished by storing the wine at about -2°C . Cold stabilization removes excess tartrates and other materials that might cause cloudiness in the bottle later.
6. Clarification: most wine consumers like a crystal-clear wine with no haze or sediment. To accomplish this objective, gelatin, isinglass, or egg white may be added to the wine. These ingredients combine with tannin and form a fine precipitate that removes some of the materials that might cause turbidity. White wines may not contain sufficient tannin. In that case, some added tannin sufficient to react with the added protein may be necessary to produce the precipitate and stabilize the wine. Bentonite, a clay, is also widely used for clarification. Ion exchange may be used to change potassium to sodium tartrate, thus increasing the solubility and reducing the likelihood of its precipitation later.
7. Bottling: wines are generally bottled in dark green or brown bottles to decrease the deleterious effects on quality that can be caused by sunlight. Small amounts of sulfite may be added to inhibit oxidation. Sweet wines may be fortified with ethanol (18–20%) or the wines may be pasteurized or sterile-filtered (the choice for high-quality wines) to prevent the growth of contaminants in the bottle.
8. Aging: aging occurs after fermentation. It can occur in tanks, in barrels, or in the bottle. The flavor may be improved through esterification reactions in which small portions of ethanol combine with organic acids in the wine. Aging improves some wines, but has little effect on others.
9. The great enemy of stability in wine is oxygen and oxidation. Barrels, tanks, or bottles holding the wine must be kept free of oxygen. This is done principally by keeping the containers full or replacing the atmosphere in the container with nitrogen or carbon dioxide. In the case of sherries, however, there is a deliberate oxidation to modify the flavor, as discussed earlier.

Sparkling Wines

Still wines given a secondary fermentation in the bottle or in a tank to produce carbon dioxide under pressure are called “sparkling.” When the secondary fermentation is produced in tanks under pressure the method is known as Charmat process, while the others where secondary fermentation occurs in bottles are named “traditional” or “champenoise” method. However, the term “Champagne” has been restricted to the sparkling wines produced in this region of France. The initial sugar content of the grapes should yield a dry still wine with about 10% v/v ethanol. The base wine, cuvee, is stabilized, fined, and filtered. It is often a blend of several wines to obtain the acidity and alcohol content desired with a clean flavor – no off-flavors or off-odors. Special wine yeasts that tend to agglomerate and thus can be more easily removed after the secondary fermentation are generally used. The same yeasts may also be used for the primary fermentation, if desired. It is particularly important that the yeasts do not produce any off-odors or off-flavors, as part of the sparkling wine flavor is derived from the yeast cells as they autolyze after the secondary fermentation. Sugar addition for the secondary fermentation is carefully controlled, as too little added will lead to a flat sparkling wine and too much sugar can lead to dangerous pressures and even explosions of the bottles. A sugar concentration of 2.4% w/v is enough to produce 7 atm pressure in the sparkling wine bottles, which generally will withstand 8 atm pressure.

In the Charmat process, the tanks offer the most efficient, lowest cost method of manufacturing sparkling wines; however, fermentation in the bottle with the longer contact of the wine with the yeast, particularly during autolysis, even though less efficient and more costly, generally yields the highest quality sparkling wines. If fermentation occurs in the bottle, the yeast cells and any precipitates must be removed after the secondary fermentation. This involves the riddling process, in which bottles are placed neck down in racks and turned a quarter turn every day or so until the yeast and all sediment in the bottle is in the neck against the cork or a crown seal. The bottles are then cooled to close to freezing, and the neck of the bottle containing the yeasts and precipitates is frozen. The bottle is then opened and held at such angle that the ice plug is blown out of the bottle. The volume lost is immediately replaced with a small quantity of sugar in wine (sometimes brandy), called “dosage.” A dry sparkling wine is called brut and contains 0.5–1.5% sugar; sec indicates 2.5–4.5% sugar; doux contains 10% sugar. The bottles are sealed with a final cork and stored on their sides to age or labeled and sent to the distributor.

Fortified Wines

Although it is possible to ferment wines to ethanol levels of 18% v/v or higher if sufficient sugar is present and a lengthy fermentation is acceptable, wines containing higher concentrations of ethanol (i.e., 17–21%) have been generally fortified to the higher ethanol concentration by the addition of wine spirits produced by distillation of wine. Wine spirits contain about 95% ethanol v/v and are generally manufactured by the distillation of lower-quality wines.

Sweet dessert wines such as port, muscatel, or sherry, with sugar contents of 12%, generally start with grapes containing more than 25% sugar. Such wines are fortified by the addition of wine spirits to an ethanol content of 17–21% v/v. The addition of alcohol stops the alcoholic fermentation and thus, the amount of sugar left can be somehow controlled by the time of alcohol addition. Thus, very sweet wines can be produced with the addition of alcohol to the must or shortly after the start of fermentation.

In other cases the alcoholic fermentation proceeds a little bit longer. Normally high ethanol concentrations do not allow the survival of spoilage microorganisms such other yeasts or acetic acid bacteria.

Flavor and Acceptability

Wine preferences are strictly personal. No other fermented beverages offer so much variety in flavor, aroma, color, sweetness, and carbonation. Consumers should drink what they like within their economic means. There are many excellent values at reasonable cost on the market. Many new wine consumers prefer the sweet wines initially, but, over time, come to prefer dry wines, which provide more of the subtle flavors and aromas characteristic of individual grape varieties and which vary from country to country. Pairing of wine and food is becoming a very attractive social activity, as many wines go along very well with some specific tastes, increasing the appreciation of both the food and wines.

Glossary

Cellulose A complex carbohydrate ($C_6H_{10}O_5$)_n of D-glucose units that constitutes the chief part of the cell walls of plants. It is used in the manufacture of numerous products, such as paper, textiles, pharmaceuticals, and explosives.

Fungi A kingdom of life forms that are eukaryotic, mycelial, or yeast-like, heterotrophic, lacking in chlorophyll, sexually and/or asexually reproductive, and mostly aerobic.

Hemicellulose Hemicellulose is a term used to refer to a wide variety of heteropolysaccharides found in association with cellulose and lignin in both woody and herbaceous plant species. These heteropolymers vary in their monosaccharide composition, glycosidic linkage composition, substitution pattern, and degree of polymerization.

Lignin A highly stable polymer of mostly methoxylated phenyl-propanoic residues, synthesized as part of the cell wall of vascular plants. The monomeric components in lignin are p-coumaryl alcohol (p-hydroxyphenyl unit), coniferyl alcohol (guaiacyl unit), and sinapyl alcohol (syringyl unit).

Lignocellulose Lignocellulosic materials consist mainly of cellulose, lignins, and hemicelluloses. The proportions among these three main components vary considerably in different plants species.

Protein engineering The design, development, and production of new protein products having properties of commercial value.

Xylooligosaccharides Xylooligosaccharides are sugar oligomers made of D-xylose units. They are produced from xylan-rich lignocellulosic materials by chemical methods, autohydrolysis, direct enzymatic hydrolysis of xylan, or a combination of chemical and enzymatic treatments. Xylooligosaccharides have great prebiotic potential and can be incorporated into many food products.

Introduction

Plant cell wall is mainly constituted by cellulose, hemicellulose and lignin. The major constituent of hemicellulose is xylan. The degradation of the xylan polymer occurs by the action of glycosyl hydrolases (GH) and carbohydrate esterases (CE), which hydrolyze glycosidic bonds and ester bonds, respectively. *Endo*-1,4- β -xylanases or merely xylanases (EC 3.2.1.8) are important enzymes for xylan depolymerization, since they catalyze the random hydrolysis of β -1,4 glycosidic bonds inside the xylan chain (Polizeli et al., 2005; Álvarez-Cervantes et al., 2016). Xylanases are mainly produced by microorganisms and have special importance in several industrial sectors, such as supplement in animal feed, manufacture of bread, food and drinks, textile industry, pulp bleaching, ethanol and xylitol production (Polizeli et al., 2005).

The market for xylanases has been growing since the beginning of the 1990s. Because of that, various commercial xylanases, obtained from distinct biological sources, and, consequently, endowed of particular intrinsic properties, are now available for individual use or associated with other enzymes forming enzymatic cocktails. The development and application of molecular biology, structural biology and protein engineering has resulted in significant progress in the research on structures and functions of xylanases with industrial use (Yang et al., 2005). In nature, xylanases are clearly involved in providing sources of carbon and energy for the organisms that produce them, acting likewise for hosts harboring xylanase-producing organisms. Moreover, xylanases seem

[☆]*Change History:* April 2017. Paulo R. Heinen, Jorge H.A. Betini and Maria L.T.M. Polizeli substituted the old Figs. 1 and 2, as well as Table 1, while Table 2 was deleted. The sections of "Hemicellulose," "Xylanases," "Structure of Xylan," and "References" were added to the article, while the sections of "Introduction," "Properties of Xylanases," "Purification of Xylanases," "Applications" and "Conclusions" were reviewed and updated. The old sections of "Mode of Action of Xylanases" and "Production of Xylanases" were expanded and renamed as "Classification and Mode of Action of Xylanases" and "Production, Cloning and Expression of Xylanases", respectively.

This article is an update of P. Bajpai, Xylanases, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 600–612.

to be involved in the invasion of plants and fruits by pathogens (Bajpai, 2009). In the present article, we described multiple forms of these enzymes, displaying their mechanism of action, substrate specificities and physicochemical characteristics. The research has mainly focused on two of the xylanases-containing glycoside hydrolase families, namely families 10 and 11, although enzymes with xylanase activity belonging to GH families 5, 7, 8, 9, 12, 16, 26, 30, 43, 44, 51 and 62 have also been identified and studied, albeit to a lesser extent.

Hemicellulose

Schulze (1891) introduced the term “hemicellulose,” denoting a substance somewhat similar in character to cellulose and that can be easily extracted, in comparison to cellulose, from plants by aqueous alkaline solutions. Hemicellulose is a class of polymers based on pentose and hexose sugars, or combinations of both, wherein xylan (polymer of D-xylose) is the most abundant polysaccharide among the constituents hemicellulosics. It is known that hemicellulose is found in the axial parenchyma, medullar rays and mainly in the plant secondary cell walls, where it can act as an adhesive by forming covalent and non-covalent bonds with lignin, cellulose and the other polymers essential to the integrity of the cellular wall (Polizeli, 2009).

The classification of the hemicellulose fractions is based on the main sugar in the polysaccharide backbone. The main monomers present in these hemicelluloses are D-xylose, D-mannose, D-glucose, D-galactose and L-arabinose. Hemicellulose includes xylan, xyloglucan, glucomannan, galactoglucomannan and arabinogalactan as its main heteropolymers. Additionally, hemicelluloses can present branched chains with D-glucuronic acid, D-galacturonic acid, 4-O-methyl-D-glucuronic acid, O-acetyl groups, ferulic acid and p-coumaric acid (Polizeli et al., 2005; van den Brink and de Vries, 2011). Hemicelluloses are non-crystalline, have lower molecular weight compared to cellulose and short lateral branches that are easily hydrolyzed (Bajpai, 2016). Furthermore, the precise composition of hemicellulose is highly dependent on the plant species and tissue of origin. Bamboo shoots, barley, oat, rice, rye, sorghum and wheat, for instance, produce satisfactory levels of glucuronoarabinoxylan (Izydorczyk and Biliaderis, 1995). Therefore, the hydrolysis of this polysaccharide produces the monomers corresponding to its classification. For example, the hydrolysis of glucuronoarabinoxylan releases D-glucuronic acid, L-arabinose, and, mainly, D-xylose units.

Hemicellulose may be extracted from plants by alkaline reagents, but autohydrolysis (thermogravimetric treatment) on agro-industrial residues has shown good results (Michelin et al., 2012), avoiding the chemical corrosions in equipment. The pre-treatments for the extraction of hemicellulose and lignin of plant cell wall are important for the separation of cellulose, which is used in the production of writing paper, as it will be reported at the end of this article. Besides, hemicellulose is important in the production of furfural, the raw material in the manufacturing of some plastics (furan resins, Bakelite) with a range of applications (Polizeli, 2009). In addition, monosaccharides obtained from hemicellulose can also be fermented by yeasts in the production of ethanol.

Structure of Xylan

Xylan is the most common hemicellulosic polysaccharide in cell walls of land plants, and is found in larger quantities in hardwoods from angiosperms (15–30% of the cell wall content) and lower abundance in softwoods from gymnosperms (7–12%) (Haltrich et al., 1996). Most xylans occur as a complex polysaccharide comprising a homopolymeric backbone of β -1,4-linked D-xylopyranosyl units substituted in varying degrees for D-glucuronopyranosyl, 4-O-methyl-D-glucuronopyranosyl, L-arabinofuranosyl, acetyl, feruloyl and/or p-coumaroyl side-chain groups. Based on the common substituents found on the backbone, xylans are categorized as arabinoxylan, glucuronoxylan and glucuronoarabinoxylan. In addition, a minority of xylans occurs as linear homoxyylan, consisting exclusively of D-xylopyranosyl units. This type of xylan is not widespread in nature and has been isolated from limited sources, such as esparto grass, tobacco stalks and guar seed husks (Motta et al., 2013). Xylans with backbone of β -1,3 linked D-xylopyranosyl units have also been reported in marine algae (Dekker and Richards, 1976). Moreover, the xylan from the marine algae *Rhodomenia palmate* is another exception with an irregular form, consisting of a linear unsubstituted structure with approximately 80% of the D-xylopyranosyl units linked by β -1,4 glycosidic bonds and 20% of β -1,3 glycosidic bonds (Ferreira-Filho, 1994).

The two main types of xylan are represented by glucuronoxylan and glucuronoarabinoxylan. Glucuronoxylan is the main hemicellulose of hardwoods, such as aspen, birch and beech. This polysaccharide generally consists of 150–200 D-xylopyranosyl residues, linked by β -1,4 glycosidic bonds. Every tenth of xylose residue carries a 4-O-methyl-D-glucuronopyranosyl attached to its 2-position, by α -1,2 glycosidic bonds. Furthermore, hardwood xylans have a high rate of substitution (70–80%) for acetyl groups, at the position 2 and/or 3 of the D-xylopyranosyl units, conferring partial solubility for these xylans in water (Coughlan and Hazlewood, 1993). Acetylation occurs more frequently at the O-3 position than at the O-2 position. Birchwood xylan, for example, contains more than 1 mol of acetic acid per 2 mol of D-xylose residue. However, these acetyl groups are readily removed when the xylans are subjected to alkali extraction (Sunna and Antranikian, 1997).

On the other hand, xylans from softwood are composed mainly of glucuronoarabinoxylans. They have a higher 4-O-methyl-D-glucuronopyranosyl content than do hardwood xylans, and are not acetylated. Likewise, D-glucuronopyranosyl units methylated at position O-4 are preferably attached to the O-2 position of D-xylose residues of the xylan backbone. Softwood xylans have L-arabinofuranosyl groups linked with the O-3 position of each tenth D-xylose residue, by α -1,3 glycosidic bonds (Puls, 1997).

The L-arabinofuranosyl substituents occur in almost 12% of the D-xylose units (Wong et al., 1988). Softwood xylans are less branched and shorter than hardwood xylans, with a degree of polymerization between 70 and 130 (Sunna and Antranikian, 1997).

According to Bajpai (2009), there is an intrinsic relationship between the xylan chemical structure versus botanical origin and cellular localization. This fact results in a certain degree of complexity of xylan-containing materials, and various xylan-related structures are described, which may differ by major or minor particulars. In some tissues of cereals and grasses, up to 50% of the biomass corresponds to xylans (Ebringerová, 2005). Generally, this xylan polymer is present in tissue secondary walls having structural functions, but it occurs in some extension in the primary walls of growing cells, seeds and bulbs of certain plant species that have reserve functions.

Xylans are covalently bound with the overlapping sheath of lignin (Biely, 1985). The layers of covalently linked xylans and lignin, and the non-covalent interaction of xylans with cellulose fibers are important for the maintenance of the integrity of the cellulose in situ, and consequently, for the protection of the fibers against the action of cellulases (Uffen, 1997). In this way, pretreatment of lignocellulosic material before enzymatic hydrolysis is an interesting step due to the complex structure of the plant cell wall, increasing the accessibility of the xylanases and other lignocellulolytic enzymes in the microcrystalline lignocellulose fibers. The pretreatment procedures aim to remove lignin and hemicellulose, reducing cellulose crystallinity and increasing the porosity of the lignocellulosic materials. There are various pretreatments described in the literature, with different characteristic for distinct biomass: physical (mechanical comminution and extrusion), chemical (acid and alkaline pretreatments, organosolv and ionic liquids), physicochemical (steam explosion, ammonia fiber explosion and liquid hot water), biological (using microbial biocatalysts, as lignin-degrading enzymes, for example) and integrated methods of these pretreatments, in order to improve the efficiency of fractionating, decrease the formation of inhibitors and shorten process time (Polizeli et al., 2016a).

Conformational analysis of xylans and other component of biomass have been carried out by several techniques. For the purpose of screening, the high throughput analysis of recalcitrance and high throughput analysis of chemical fingerprint may be used, which are a modified pyrolysis molecular beam mass spectrometry method to detect the presence of cellulose, xylan, lignin, syringyl and guaiacyl units. The glycome profiling is also a technique based on the combination of monoclonal antibodies and carbohydrate-binding modules for monitoring epitopes of cell wall glycans. However, downscaled compositional analysis includes, among others, the high-resolution methods, such as (1) sequential extraction with solvents and reagents; (2) gel permeation chromatography coupled to polymer derivatization and light scattering, refractive index and viscometry detectors to provide molecular weights and consequent DP of polymers; (3) spectroscopy, such as liquid-state NMR Spectroscopy coupled with extraction techniques (which have gained attention due to their low destructive characteristic and level of information generated) and solid-state NMR Spectroscopy (which uses the native cell wall to analyze the spatial dimensions between biopolymers, ultra-structures and pore structures), while the Fourier-Transform Infrared Spectroscopy (FTIR) offers functional group and chemical linkage profiles; there is also the X-ray diffraction allowed to determine crystallinity index; and (4) imaging of biopolymers, which includes the scanning electron microscopy, transmission electron microscopy, time-of-flight secondary ion mass spectrometry (ToF-SIMS), MALDI-imaging MS (MALDI-IMS), mode-synthesizing atomic force microscopy (MSAFM), a variant of the atomic force microscopy and the confocal laser scanning microscopy (CLSM) (Polizeli et al., 2016a).

Xylanolytic System

Due to the heterogeneity and complexity of xylan structures, their complete hydrolysis requires several enzyme activities that act cooperatively and synergistically to convert xylan into its monomeric sugars of origin. The degradation of the xylan polymer occurs through the action of *endo*-1,4- β -xylanases, which cleaves the xylan backbone into smaller xylooligosaccharides, and β -xylosidase, which cleaves the xylooligosaccharides into D-xylose residues. In addition, accessory enzymes contribute to the release of all substitutions present on the main backbone and, therefore, achieve the complete degradation of the xylan polymers (Polizeli et al., 2016b).

The xylanolytic system includes the (1) glycosyl hydrolases (GH), which hydrolyze glycosidic bonds, and (2) carbohydrate esterases (CE) which hydrolyze ester bonds of acetate, ferulic and p-coumaric acid side groups. Here, the GHs are described first and, thereafter, the action of CEs.

- *Endo*-1,4- β -xylanases (E.C.3.2.1.8) are the main glycosyl hydrolases of the xylanolytic system, and are commonly named, in the literature, only by "xylanases." These *endo*-enzymes hydrolyze β -1,4 glycosidic bonds inside the xylan chain producing xylooligosaccharides. The rate of the hydrolysis reaction normally decreases with the decrease in the chain length of xylooligosaccharide substrates (Polizeli et al., 2005; Nacke et al., 2012). In general, *endo*-1,4- β -xylanases do not hydrolyze xylobiose, and the hydrolysis of xylotriose is in most cases negligible or at least limited. Both the length and the type of the products released depend on the mode of action of each xylanase (Bajpai, 2009).
- Xylan-1,4- β -xylosidases (E.C.3.2.1.37) have been classified into the GH families 3, 39, 43, 52 and 54 based on the amino acid sequence similarities (Xia et al., 2015). β -xylosidases act cooperatively with *endo*-1,4- β -xylanases, converting the xylooligosaccharides from the non-reducing end until D-xylose units. Some β -xylosidases show transxylosylation at high substrate concentrations, which can be used to produce novel xylose-containing xylooligosaccharides (Kurakake et al., 2005).
- α -glucuronidases (E.C.3.2.1.139) hydrolyze the α -1,2 glycosidic bonds between xylose residues and glucuronic acid or 4-O-methyl-D-glucuronic acid in glucuronoxylan and/or glucuronoarabinoxylan (Polizeli et al., 2005; Gírio et al., 2010).

Fig. 1 Schematic representation of the xylan polymer and xylanolytic system enzymes.

- α -L-arabinofuranosidases (E.C.3.2.1.55) are enzymes that hydrolyze the terminal non-reducing L-arabinofuranosyl groups from L-arabinose-containing polysaccharides attached to the O-2 and/or O-3 positions of D-xylose residues (Margolles and de los Reyes-Gavilán, 2003; Polizeli et al., 2005; Burlacu et al., 2016). The removal of L-arabinose side residues allows a better access of *endo*-1,4- β -xylanases and β -xylosidases to the xylosidic linkage in the xylan backbone (Sun et al., 2012).
- Acetyl-xylan esterases (EC 3.1.1.72) are carbohydrate esterases that cleave the ester linkages of the xylan acetyl groups, releasing acetyl substituents from the position O-2 and/or O-3 of D-xylose residues in glucuronoxylan (Polizeli et al., 2005).
- Feruloyl esterases (EC 3.1.1.73) and p-coumaric acid esterases (EC 3.1.1.-) cleave ester bonds between ferulic acid and L-arabinose residues and p-coumaric acid and L-arabinose residues of xylan, respectively (Segato et al., 2014; Burlacu et al., 2016).

Fig. 1 shows a hypothetical plant xylan structure and different substituent groups with the possible sites of attack by microbial xylanolytic enzymes.

Classification and Mode of Action of Xylanases

Endo-1,4- β -xylanases, as GH members, have been classified based on at least three criteria: (1) molecular weight and isoelectric point, (2) kinetic properties or the substrate specificities and (3) similarities in primary structure together with the conservation of the catalytic residues and catalytic mechanism (Collins et al., 2005; Motta et al., 2013). Updated information on the functional characteristics, sequence annotations and family classification of enzymes may be found in the carbohydrate-active enzyme (CAZy) database (Cantarel et al., 2009). According to the search in this database by Motta et al. (2013), *endo*-1,4- β -xylanases (EC 3.2.1.8) are related to GH families 5, 7, 8, 9, 10, 11, 12, 16, 26, 30, 43, 44, 51 and 62.

Literature survey shows that only the enzymes classified in families 5, 7, 8, 10, 11 and 43 contain truly distinct catalytic domains with *endo*-xylanase activity, while the enzymes classified in families 16, 51 and 62 seem to be bifunctional enzymes containing two catalytic domains. Members of families 9, 12, 26, 30 and 44 should be considered as having a residual or secondary xylanase activity (Collins et al., 2005; Motta et al., 2013). On the basis of primary sequence homology and hydrophobic cluster analysis, *endo*-1,4- β -xylanases have mainly been grouped into glycoside hydrolase families GH10 and GH11, which correspond to former families F and G, respectively (Wang et al., 2014).

Members of families 5, 7, 8, 10, 11 and 43 differ in their physicochemical properties, structure, substrate specificity and mode of action (Taibi et al., 2012). Generally, their mode of action results in the release of products with either retention (GH families 5, 7, 10 and 11) or inversion (GH families 8 and 43) of the substrate anomeric configuration (Collins et al., 2005; Motta et al., 2013; Álvarez-Cervantes et al., 2016; Heinen et al., 2017). Families 5, 7, 10 and 11 contain enzymes that catalyze the xylan hydrolysis with

Fig. 2 A hypothetical model of double-displacement reaction mechanism for retaining xylanases. Figure was prepared with ChemSketch version 12.0.

the involvement of a pair of glutamate residues at the active site. That indicates a double-displacement mechanism, in which a covalent glycosyl-enzyme intermediate is formed and subsequently hydrolyzed via oxocarbenium-ion-like transition state. Primarily, two carboxylic acid groups are involved in the formation of the intermediate, wherein one of them acts as a general acid catalyst by protonating the substrate while the second performs a nucleophilic attack, which results in the departure of the leaving group and the formation of the α -glycosyl enzyme intermediate (β to α inversion). In the second step, the first carboxylate group now functions as a general base, subtracting a proton from a nucleophilic water molecule, which attacks the anomeric carbon. That leads to a second substitution, in which the anomeric carbon again passes through a transient state to give rise to a product with the β configuration (Collins et al., 2005; Motta et al., 2013; Álvarez-Cervantes et al., 2016). Thus, the overall result of this catalytic mechanism is the retention of the configuration in the anomeric center, as shown in Fig. 2.

Xylanases from the GH11 family have low molecular weight, high pI values and a tertiary structure known as β -jelly-roll, while those from the GH10 family have high molecular weight, lower pI values and display an (α/β) 8-barrel fold (Collins et al., 2005; Motta et al., 2013; Álvarez-Cervantes et al., 2016).

The glycoside hydrolase family 10 consists of *endo*-1,4- β -xylanases (EC 3.2.1.8), *endo*-1,3- β -xylanases (EC 3.2.1.32) and cellobiohydrolases (EC 3.2.1.91). Although the main members of this family are *endo*-1,4- β -xylanases, studies about substrate specificities have revealed that these may not be highly specific for xylan and may also be active on cellulose substrates of low molecular weight (Collins et al., 2005; Cheng et al., 2009; Motta et al., 2013). Furthermore, these enzymes are highly active on xylooligosaccharides of low polymerization degree, thereby indicating that their substrate-binding sites are small and apparently not so deep clefts (Biely et al., 1997; Álvarez-Cervantes et al., 2016).

In contrast to all other families, the GH11 family is monospecific since it consists only of *endo*-1,4- β -xylanases (EC3.2.1.8). Its members are considered as true xylanases because they are exclusively active on xylose-containing substrates. Compared to other xylanases, GH11 members display several interesting biochemical properties, such as high catalytic efficiency and substrate selectivity, a small size and a variety of optimum pH and temperature values, making them suitable to various conditions and in many industrial applications (Shrinivas et al., 2010; Motta et al., 2013). These enzymes are most active on xylooligosaccharides with higher degree of polymerization. Indeed, it has been found that they have larger substrate binding clefts than do higher molecular weight xylanases (Biely et al., 1997; Shrinivas et al., 2010; Motta et al., 2013).

Properties of Xylanases

Microbial xylanases have been extensively studied in diverse microorganisms. Table 1 illustrates the intrinsic characteristics of fungal xylanases from some species of *Aspergillus*, *Fusarium*, *Penicillium*, *Scytalidium*, *Talaromyces*, *Thermomyces* and *Trichoderma*. The majority of the xylanases purified from fungi present molecular weight around 20–40 kDa, but xylanases with lower and higher molecular weight have also been found, as the minor xylanase (7.7 kDa) isolated from *Aspergillus caespitosus* (Sandrim et al., 2005) and the xylanase (66 kDa) from *Aspergillus fumigatus* (Thiagarajan et al., 2006), respectively. In general, these enzymes are monomeric

<i>Trichoderma reesei</i>	32.0	9.1	6.0	55	Birchwood xylan	2.02	10	Xu et al. (1998)

proteins and display very varied pI values. Some fungal xylanases have acidic pI (3.7–3.8), as in *Penicillium funiculosum* and *Thermomyces lanuginosus*, while others have basic pI (7.7–9.5) (Table 1).

The optimum pH values are generally around 5.0–7.0, for most fungal xylanases. However, there are exceptions with extreme pH values. Al Balaa et al. (2009), for example, reported an acidic pH value of 3.2 to xylanase from *Scytalidium acidophilum*. In contrast, xylanases with alkaline pH values of 8.0 and 8.5 have also been isolated from *Fusarium graminearum* (Beliën et al., 2005) and *Penicillium citrinum* (Dutta et al., 2007), respectively. Moreover, xylanases are normally stable in the range of pH 2–9 (Bajpai, 2009). The optimum temperature range of most fungal xylanases is between 50 and 60°C, while the xylanases from thermophilic fungi produce enzymes with maximum activity at higher temperatures, as reported for *Talaromyces thermophilus* and *T. lanuginosus* (Table 1). Regarding thermal stability, microbial xylanases generally have a wide range of temperature tolerance (20–60°C).

Production, Cloning and Expression of Xylanases

Xylanases are produced by various organisms, such as fungi, bacteria, yeast, protozoa, snails, crustaceans, insect and seeds (Suzuki et al., 1991; Devillard et al., 1999; Suda et al., 2003; Brennan et al., 2004; Crawford et al., 2005). Filamentous fungi are particularly interesting producers of these enzymes from an industrial point of view, due to the fact that they secrete xylanases into the medium. Furthermore, xylanase levels from fungal cultures are generally much higher than those from yeasts or bacteria. In addition, fungi tend to produce mixtures of xylan-degrading enzymes, different xylanases combined with accessory enzymes for debranching substituted xyans (Haltrich et al., 1996).

The cost-effectiveness, ease of use and eco-friendliness of enzymes are factors that justify the use of a biocatalytic process. In order to meet industrial requirements, an ideal xylanase should have specific properties, such as stability over a wide range of pH values and temperatures, high activity, and strong resistance to metal ions and chemicals. Therefore, most of the xylanases reported do not possess all these physicochemical and functional characteristics required by industries. Moreover, the native enzymes are not

sufficient to supply the demand, due principally to low yields and incompatibility of the standard industrial fermentation processes (Motta et al., 2013).

In this context, molecular approaches can be implemented to design xylanases with the characteristics required. Recombinant DNA techniques offer opportunities for the construction of microbial strains with selected enzyme machinery, and also allow large scale expression of these enzymes in both homologous and heterologous protein expression hosts (Juturu and Wu, 2012). In xylan bioconversion, for instance, the main objective for recombinant DNA technology is improvement of the fermentation characteristics of xylose-fermenting industrial strains by introducing xylanase and β -xylosidase genes, so that the direct fermentation of xylan is possible (Bajpai, 2009).

Both the prokaryotic and eukaryotic organisms are commonly used as hosts for the recombinant protein expression. The system selection depends on protein, desired yield and the requirements for its function activity (Chakravorty and Patra, 2013). *Escherichia coli* is the prokaryotic organism most widely used for expressing recombinant proteins. This host, as a recombinant expression platform, has multiple advantages, such as rapid growth on inexpensive media, simple techniques required for transformation, easy isolation and purification of expressed enzymes. Nevertheless, it does not provide efficient and functional heterologous expression of many xylanases. This problem can be due to the repetitive appearance of rare codons and the requirement for specific post translational modifications such as disulfide bond formation and N-glycosylation. *E. coli* can only perform simple O-glycosylation, while the *Lactobacillus* species and *Bacillus subtilis* are able to perform N-glycosylation and possess Generally Regarded As Safe status (GRAS), making them more accepted for use in food and pharmaceutical industries. Moreover, xylanase expression levels are relatively higher in *Lactobacillus* species and *B. subtilis* than in *E. coli* (Juturu and Wu, 2012; Motta et al., 2013).

On the other hand, protein expression in yeast and fungal systems are also highly attractive, once they provide additional benefits over bacterial expression systems. Among these benefits are the ability to perform eukaryotic post-translational modifications and the ability to secrete proteins into the fermentation media. Yeast is free of toxins and the majority has GRAS status. Accordingly, *Saccharomyces cerevisiae* for secreting high amounts of enzymes into the culture medium is an ideal microorganism in the large-scale production of xylanases at low costs. Indeed, it has already been established as an industrial microorganism. *Pichia pastoris* has also emerged as an excellent host for the commercial production of xylanases. However, the expression under the methanol-inducible alcohol oxidase promoter, the first enzyme involved in the methanol utilization pathway, has limited the use of this recombinant expression platform in a large scale due to the health and fire hazards of methanol. Recently, fungal expression systems have been preferred for expressing xylanases. Additional advantages of fungal systems are experiences in handling fungal cultivation and feasibility of using native xylanase expressing machinery for functional expression of foreign xylanases from remote sources (Juturu and Wu, 2012; Motta et al., 2013). For instance, the xylanase genes from *Malbranchea pulchella* and *Aspergillus niger* were cloned and successfully expressed in *Aspergillus nidulans* (Damasio et al., 2011; Ribeiro et al., 2014).

Purification of Xylanases

The commercial and industrial applications usually require the development of cost-effective strategies not only for the large-scale production of xylanases, but also for their purification. Utilization of crude enzyme for some applications might be beneficial, such as bioethanol production and waste treatment, where synergistic effects of glycoside hydrolases are desirable for lignocellulosic biomass deconstruction. On the other hand, a high degree of purity is required for the food and pharmaceutical industries, since the presence of interfering enzyme activities and undesirable secondary metabolites in the preparations prevent their application in such industries (Kumar and Sharma, 2015; Yegin, 2017).

Xylanase purification schemes have generally used different methods including salt fractionation, ion-exchange, gel filtration and hydrophobic interaction chromatography. The low molecular weight of certain xylanases has also enabled their separation from other proteins using ultrafiltration (Bajpai, 2009). However, the rapid and economical purification of microbial xylanases represents a persistent challenge for their industrial applications. Purification of target enzymes from a pool of proteins typically involves several tedious purification steps, and each of which can be costly and time-consuming, decreasing the final yield of the product (Banki et al., 2005; Juturu and Wu, 2012). In this context, the importance of affinity chromatography has increased over the years due to the advantages of recombinant DNA technology. The sequence of protein labels may be incorporated into the gene of interest, which will make purification and isolation of the target protein in a much easier way (Ravindran and Jaiswal, 2016). In particular, the histidine (His) tag has been widely used to facilitate purification of recombinant enzymes. This tag is comprised of a sequence of six consecutive histidine residues which are added to either the N or C terminal of recombinant protein sequence and exhibit high affinity toward metal ions such as Co^{2+} , Ni^{2+} , Cu^{2+} and Zn^{2+} (Terpe, 2003; Saraswat et al., 2013). After binding, the tagged enzymes can be eluted from immobilized metal affinity chromatography under mild conditions with a high degree of purity and recovery. This single-step purification strategy helps to decrease the processing cost, thus broadening the scope of xylanase applications (Yegin, 2017).

Applications

Over the last few years, interest in xylanases from microorganisms has rapidly increased because of their potential application in the bioconversion of lignocellulosic materials into value-added commodities, as well as the traditional applications in

food, feed, pharmaceutical and paper industries. These enzymes not only make the process environmentally benign, but also play an important role in improving the productivity and reducing the cost of product formation (Deswal et al., 2012; Motta et al., 2013).

Pulp and Paper Industry

Xylanases are commercially used in the bleaching of the kraft pulp. The use of xylanases is often referred to as a prebleaching process because the nature of its effect, which consists of enhancing the efficiency of bleaching chemicals rather than removing lignin directly (Bajpai, 1999). These enzymes do not attack the lignin-based chromophores but rather the xylan network by which the residual lignin particles are surrounded and trapped (Bajpai et al., 2006). A limited hydrolysis of the xylan network is often enough to ease the subsequent chemical attack on lignin with various bleaching chemicals, without sacrificing the yield (Bajpai, 1999, 2009).

The application of enzymes in pulp bleaching was first published by Viikari et al. (1986). In that study, the results indicated that xylanases are capable of enhancing the effects of bleaching, resulting in savings of 10–20% of chemicals. Subsequent research was directed at enzymes that oxidize lignin such as laccases, but these enzymes have only a limited effect on the pulp bleaching (Viswanath et al., 2014). Following that, an important advance was achieved with the discovered of a mediator called 2,2'-azinobis(3-ethylbenzthiazoline-6 sulfonate) (ABTS), which increases the efficiency of laccases in the bio-bleaching (Bourbonnais et al., 2000). The Finnish forest companies were the first in the world to start mill-scale trials, in 1988. In North America, the first mill trials with xylanases were carried out in Port Alberni, in 1991, and ongoing usage in some mills started in 1992 (Bajpai, 2009). Currently, a significant number of European, North American, South American and Japanese mills are using xylanases as a prebleaching process.

The various pulp and paper industries have different strategies and processes regarding the sequential stages of bleaching cellulose pulp. Basically, the chemical elements most commonly used in traditional bleaching are: sodium hydroxide (NaOH), sodium sulfide (NaH₂S) (high-temperature cooking stage and pressure), chlorine dioxide (ClO₂), hydrogen peroxide (H₂O₂), oxygen (O₂) and ozone (O₃) (bleaching stage). The most commonly used extraction agent is sodium hydroxide (Polizeli et al., 2005; Polizeli, 2009). The companies differ in the bleaching process according to the desired degree of pulp and paper whiteness. The most common sequences are those divided into 4 or 5 stages according to the chemical combination chosen.

The control of bleaching and bleaching reactions is important in the pulp and paper industry to ensure the quality of the final product (de Vaal and Sandroek, 2007). The main variables in each stage of bleaching are: chemical additives, reaction time, pulp consistency, intensity of agitation, pH and reaction temperature. The kappa number and pulp viscosity are control parameters widely used to evaluate the pulp quality during the stages of its production. The first parameter determines the amount of residual lignin in the fibers that make up the cellulosic pulp, while the viscosity measures the degree of degradation these fibers, since the more degraded the fibers are in the cellulosic pulp, the lower its viscosity and whiteness will be.

At present, many sectors of the pulp and paper industries have adhered to the production and processes that no longer use chlorine as an oxidizing element in the bleaching stages of cellulosic pulp. That can be considered an ecological process and is known as EFC (Elementar Free Chlorine). However, the use of chlorine dioxide is still quite common. In this context, the use of enzymes such as xylanases at certain stages of the bleaching process allows the decrease in the amount of chemicals, thus reducing the effluents to be treated and, consequently, their environmental impacts (Bajpai, 2009; Gangwar et al., 2014).

Food Industry

Xylanases have applications in different sectors of food industry. Using xylanases in the bread-making industry significantly improves the desirable texture, loaf volume and shelf life of the bread (Dobrev et al., 2007; Heinen et al., 2014). Xylanases, together with pectinases, cellulases and amylases, are used for the clarification of juices (Motta et al., 2013). They are also used in the brewing industry in order to improve filtration efficiency (Wang et al., 2016). In addition, in recent years, there has also been an interest in the production of D-xylose and short-chain xylooligosaccharides by the enzymatic hydrolysis of xylan. Xylooligosaccharides are important ingredients for the development of novel functional foods due to their prebiotic effects, since they increase mineral absorption, induce peristalsis and act as regulatory substrate in the intestinal flora (Heinen et al., 2017; Yegin, 2017). The D-xylose residues, in turn, may be converted to xylitol, a valuable sweetener widely used as a sugar substitute for the diabetic population (Meyrial et al., 1991; Sena et al., 2016).

Pharmaceutical Industry

The features of xylooligosaccharides such as resistance to heat up to about 100°C and stability over a wide range of pH (2.5–8.0) make them good candidates for drug formulation and pharmaceutical applications. XOS, as bioactive components, can thus be used as a preventative agent against oxidative stress, anemia, arteriosclerosis, atherosclerosis, diabetes, osteoporosis and certain types of cancers (Deutschmann and Dekker, 2012). It was also demonstrated that XOS can have immunomodulatory activity, anti-microbial activity, growth regulator activity and other biological activities like anti-allergic, anti-inflammatory,

anti-hyperlipidemic and cosmetics (Aachary and Prapulla, 2011; Deutschmann and Dekker, 2012; Kumar et al., 2012; Gupta et al., 2016).

Animal Feed

Animal feed, including cereals like wheat, triticale, rye, barley and soy-based diet, are rich in biomass composed by cellulose, hemicellulose and lignin. However, the viscous properties of these lignocellulosic materials hinder their digestion (Kalim et al., 2015). The addition of xylanases ensures the utilization of nutrients trapped inside the plant cells, while they also reduce the viscosity created by non-starch polysaccharides (NSPs) in the animal's digestive tract (Pirgozliev et al., 2015). Addition of exogenous xylanases to the animal diets has shown beneficial effects on feed conversion efficiency, growth and weight gain in monogastric animals (Yegin, 2017). Furthermore, specific xylooligosaccharides can be produced through the use of appropriate xylanases in pig and poultry diets to improve their prebiotic action (Choct, 2015).

Xylanases can also be used to improve the nutritional properties of agricultural silage. Treatment of forages with hydrolytic enzymes results in silage of better quality and improves the subsequent rate of plant cell wall digestion by ruminants (Kalim et al., 2015). There is a considerable amount of sugar sequestered in the xylan of plant biomass. In addition to converting hemicellulose into nutritive sugars that the cow or other ruminant can digest, xylanases also produce nutritionally suitable compounds for the desired ruminal microflora, which in turn further assist digestion (Bajpai, 2009; Kalim et al., 2015).

Bioethanol Production

Currently, important variables such as global climate change, scarcity of petroleum reserves, and increase in the costs of fuels have stimulated an unprecedented research into the production of alternative fuels, preferably from renewable energy sources (Polizeli et al., 2016b; Uday et al., 2016). For such reason, bioethanol is gaining great importance as a renewable and sustainable source of fuel (Kanimozhi and Nagalakshmi, 2014). Despite the notorious worldwide production of first-generation ethanol, from sucrose and starch, the production of second-generation ethanol has a greater advantage because it does not compete with food production and can provide environmental, economic and strategic benefits for the production of biofuels (Sarkar et al., 2012; Motta et al., 2013).

In second-generation bioethanol production, the first step is the delignification of lignocellulose, to release cellulose and hemicellulose from their complex with lignin. The second step corresponds to the hydrolysis of carbohydrate polymers to produce reducing sugars, as D-glucose, D-xylose and L-arabinose, followed by the fermentation of mixed pentose and hexose sugars by yeast up to bioethanol (Polizeli et al., 2016b). In this context, xylanases together with other accessory enzymes can efficiently be used to increase the depolymerization of the carbohydrate polymers from lignocellulosic biomass, leading to a more economical and viable production of bioethanol (Motta et al., 2013).

Conclusions

In nature, endo-1,4- β -xylanases are synthesized by diverse organisms, but those with biotechnological applications are obtained from microorganisms, mainly filamentous fungi because they may secrete enzyme to the medium. In general, such enzymes are produced in submerged or solid-state fermentation using xylan extracted from different plants, but in order to reduce costs, agro-industrial residues as sugar cane bagasse, wheat straw and others, may be used as inductor. Innumerable applications are attributed for xylanases, which have special importance in several industrial sectors, such as supplement in animal feed, manufacture of bread, food and drinks, textile industry, pulp bleaching, effluent treatment, agro-waste treatment, ethanol and xylitol production. Currently, this enzyme have been widely used in the cellulose-pulp bleaching with the objective of reducing the large amount of chemical solvents applied in the conventional Kraft process. The use of chlorine dioxide results in the production of organochlorine compounds from the degradation of lignin, and these are highly toxic and mutagenic, requiring effluent treatments from the paper-making plant to make the paper production a less harmful process to nature. Regarding this problem, environmental restrictions about the use of chlorine compounds in the paper industry are being implemented, but a drastic change in the existent mentality from people is necessary.

Another important focus is the prospection of novel xylanases with suitable properties for biorefinery, aiming at biofuel production from biomass. In this context, microorganisms with high xylanase secretion are desirable, and enzymes with high resistance to end-products, as D-xylose. Moreover, for this target to be successful, the prospection of thermophilic microorganisms is necessary, as well as searches for enzymes with high resistance to the temperatures and pH range, development of recombinant DNA technologies for super-expression of these enzymes and yeasts with metabolism regulated adequately for the fermentation of pentasaccharides released after the action of hydrolytic enzymes. Concluding, in order to be effective in the several industrial sectors reported, xylanases must not be used alone, but in combination with other enzymes, forming an enzymatic cocktail for complete degradation of biomass. Currently, the commercial cocktails available for the bioenergy field are still catalytically incomplete (and expensive), and more studies about enzymes structural and functional characterization will provide additional tools to fill the scientific knowledge gap.

INDEX

This index is in letter-by-letter order, whereby hyphens and spaces within index headings are ignored in the alphabetization, and it is arranged in set-out style, with a maximum of four levels of heading. Location references refer to the volume number, in bold, followed by the page number. Page numbers suffixed by *b*, *f*, *ge* and *t* refers to boxes, figures, Glossary and tables terms respectively. *vs.* indicates a comparison. **Bold locators** refers to main articles.

 primary active transporters, 3:157, 3:159*f*, 3:161–165

Cytoplasmic membrane transporters
(*Continued*)
secondary active transporters, 3:157,
3:159f, 3:166–167
structural analysis, 3:159
types of, 3:157, 3:159f
Cytoskeletal proteins, 3:558–560
placement, *Caulobacter crescentus*,
1:622–623
Cytoskeleton
actin, 3:314–316
GFP, 3:311
intermediate filaments, 3:317
tubulin, 3:311–314
wall-less mycoplasmas, 3:317–318
Cytosol, 3:399
Cytotoxic lymphocytes (CTLs), 4:18
Cytotoxic necrotizing factor (CNF),
2:201–202
Cytotoxic T-lymphocyte-associated antigen-4
(CTLA-4), 3:106
Cytotoxin associated gene A (CagA) protein,
2:519–521
Cyt toxins, 1:309, 1:312

D

Dagger-type nematodes, 4:181
Daily cell cycle rhythm, 1:686
Dairy industry, 3:174, 3:176
Dairy strains, 3:179–180
Dam. *See* DNA adenine methyltransferase
(Dam)
Dam gene
bacteriophage DNA packaging, 3:88–89
nucleoid structure, 3:87
posttranscriptional regulation, 3:88, 3:89f
replication initiation, 3:86
transcription, 3:86–88, 3:86f
Damp building syndrome, 3:269
Danger-associated molecular pattern
(DAMP), 3:445, 3:450
Dark beers, 1:469
Dark energy, 3:26–27
Dark-field microscopy, 4:252–253
Dark green islands (DGIs), 4:188
Dark metabolism, of cyanobacteria,
1:808–809
Darnavir
adverse effects, 1:220
chemistry, mechanism of action, and
antiviral activity, 1:220
resistance, 1:220
data, 1:676
Database of Single Nucleotide Polymorphism
(dbSNP), 2:393
Day-care centers, 4:329–330
Dcw cluster, 1:378, 1:378f
D,D-endopeptidases and carboxypeptidases,
3:467–468
DdrA, 2:255–256
Deacetoxycephalosporin C synthase, 2:669
Deaminase, 1:146
Debaryomyces hansenii, 3:178–179
Debranching enzymes, amylase, 1:111
Decarboxylation, ion translocation linked to,
2:144
Decay accelerating factor (DAF), 1:724
Decoding center, 4:477
Decontamination, 2:280
Deep biosphere
endospores to, 3:24–25
hot spots, 3:20–22
interaction, 3:21f
physiological adaptations, 3:26
prokaryotes, cultivation of, 3:25–26
significance of, 3:26–27
Deep Lake, 2:270
Deep ocean adaptation, 1:16–17
Deep-sea hydrothermal vents, 2:267
Deep-sea hypersaline anoxic lakes (DHAs),
2:270
Deep sea microbiota, organic matter, 1:17
Deep sediments, 3:20
Defense Advanced Research Projects Agency
(DARPA), 1:524
Degradation, 1:762, 1:770–771
microbial degradation of coatings,
1:770
in organic matter, 3:23f
of protective coating, 1:769
Degradosome, 3:688
Degradosome-like network (DLN),
4:167–169
Dehalococcoidia, 1:653
Dehydration, 3:480
Deinococcus sp., 2:256
D. radiodurans, 2:255–256
Delavirdine
adverse effects, 1:211
chemistry, mechanism of action, and
antiviral activity, 1:211
clinical indications, 1:211
resistance, 1:211
Deleya (*Pseudomonas*) *marina*, 1:768
Delta antigen, 4:560
Deltaproteobacteria, 1:393
Deltaretroviruses, 2:615, 4:110
Dementias, 4:119
Demyelination, 1:34
Denaturing gradient gel electrophoresis
(DGGE), 3:23, 3:47, 3:573
Denaturing gradient gel electrophoresis
(DGGE)-PCR, 3:180
 δ -Endotoxins, 1:307
Dendritic cells (DC), 2:344, 2:520, 2:530,
2:623, 2:626, 3:498–499
Dengue fever (DF), 1:239–240
Dengue hemorrhagic fever (DHF), 1:236
Dengue shock syndrome (DSS), 1:239–240
Dengue virus (DENV), 1:235, 1:239–240,
2:537
Denitrification, 2:141, 2:302, 3:307–309
Denitrifying bacteria, 1:497
De novo metagenome assembly, 2:438
Dense blooms of diatoms, 1:71
Dense granules, 4:433
Dental biofilms, 1:513–514
Dental caries, 3:331, 3:343–345

diagnosis, 3:349
prevention and control of, 3:349–350
Dental plaque, 3:330–332, 3:340,
3:343–344, 3:345f, 3:349–350
Dentilisin, 4:287
Deoxyadenosine methyltransferase,
1:675–676
Deoxynivalenol, 3:272f
Deoxyribonucleic acid (DNA) viruses,
4:559–562, 4:565–567
Deoxyxylulose phosphate (DXP), 3:591–592
Dependoviruses, 4:540–541
Depolarization theory, 1:767
Depolymerases, extracellular polymeric
substance (EPS), 1:447
Dermacentor variabilis, 4:532, 4:533f
Dermacentroxenus typhi, 4:529
Dermatan sulfate, 2:684–685
Dermatophytosis, 1:795–796, 1:795t
Derwent World Patents Index (DWPI), 3:439
Desert cyanobacteria, 2:242f
Desert soils, microbiota of, 2:240–243
Desiccation, 2:252–253, 2:255
Desiccation-resistant terrestrial cyanobacteria,
1:815
Desulfobacteriales, 1:304
Desulfobacter hydrogenophilus, 1:297, 1:304,
1:304t
Desulfovibrio desulfuricans, 1:767
Desulfurobacteriaceae, 1:226–228, 2:264
Desulfurococcales, 2:266
Detective quantum efficiency (DQE), 4:259
Detergent applications, amylase, 1:121
Deterioration, 1:492, 1:494, 1:769
of building stone, 1:499
of inorganic materials, 1:768
of metal materials, 1:500
stone, 1:491
Device-associated biofilms, 1:515–517
Devil facial tumor disease (DFTD), 4:543f,
4:544–545
Dextran, 3:670–671, 3:670f
D-glucuronic acid, 4:410–411
D'Herelle, Félix, 3:487
Diacetyl, 1:474
Diadenylate cyclases, 4:235
Diagenetic mineral formation, 3:513
Diagnostic microbiology, 2:1
detection and identification,
microorganisms, 2:11–12
development of, 2:2–3, 2:2t
laboratory automation, 2:13–14
microorganism quantification, 2:12
microorganisms, direct identification of,
2:3–10
nongenomic molecular testing, 2:10–11
rapid, on-demand, and point-of-care
testing, 2:13
syndromic, multiplex testing, 2:12–13
Diarrhea
adenovirus, 2:161
human astrovirus (HAstV), 2:158
noroviruses and sapoviruses, 2:156–157
rotavirus, 2:159–160
